The Plateau pika is considered by Smith and Foggin (1999) to be a keystone species in its habitat (Fig. 4). This is because it makes burrows that turn the soil and thus help soil mixing and aeration, enhanced soil water infiltration, and enhanced seed dispersal, all of which foster greater plant productivity, diversity and abundance. Jiang and Xia (1987) determined that the foraging of plateau pikas may play an important role in the stabilization of alpine meadow plant communities. This species’ old, abandoned burrows become the primary homes to a wide variety of small birds and lizards. It serves as the principal prey for nearly all of the plateau’s predator species. Thus, this pika makes a positive contribution to ecosystem-level dynamics. The burrows constructed by the plateau pika offer breeding habitat for many species. Hume’s ground jay (*Pseudopodoces humilis*) and several species of snow-finch (*Montifringilla adamsi*, *M. blanfordi*, *M. davidiana*, *M. ruficollis*, *M. taczanowski*) all nest mainly in the burrows excavated by this pika. Two species of lizards, including the snow lizard (*Phrynocephalus vlangalii*) and the multiocellated racerunner (*Eremas multiocellata*) use pika burrows for cover and as breeding sites. Taken altogether, the plateau pika serves to increase the biodiversity of the localities where it lives.

Most predators in the Asian alpine, especially on the Tibetan plateau, rely heavily on pikas for food. Pikas are not only the most abundant source of food for predators during the summer, but as pikas do not hibernate, they become almost the sole source of winter food for many predatory species. These predators include steppe polecat (*Mustela eversmanni*) weasels (*Mustela altaica*, *M. eversmanni*), foxes (*Vulpes ferrilata*, *V. vulpes*), and Pallas’s cat. All of these rely heavily on pikas for food. Many larger mammalian predators such as wolves, snow leopards, and brown bears also prey on animals as small as pikas. Snow leopards largely specialize on big game (Mallon et al., 2016), and pikas act only as a buffer species. However, pikas comprise over 50% of the diet of wolves in some areas, and brown bears appear to be particularly reliant on pikas for food. One study in the Chang Tang region found that pikas comprise almost 60% of brown bear diet. Most large predatory birds on the Tibetan plateau depend upon pikas as a food source, including golden eagles (*Aquila chrysaetos*), upland buzzards (*Buteo hemilasius*), saker falcons (*Falco cherrug*), goshawks (*Accipiter gentilis*), black kites (*Milvus migrans*), and little owls (*Athene noctua*).

Large Mammals (Fig. 5)

In contrast to the small mammals, the large mammals have a far smaller surface-to-volume ratio, so they lose much less internal metabolic heat to the environment. Many of these larger mammals remain active in the winter, such as the yak, chamois, wild sheep, ibex, deer, and their predators. Their exposure to low winter temperatures is not without cost, however. All of these animals lose weight through the cold months. Grazers must continue to forage for food throughout the year, in order to maintain the gut micro-organisms that are essential to their digestion. Snow conditions are critical to the health and survival of grazing mammals in the alpine. When snow cover is too deep, many grazers may starve before the end of the winter season.

Bovids, gazelles, and wild yaks

Of the fourteen species in this group of even-toed ungulates, four are considered “Vulnerable” and one is considered “Endangered” by the IUCN. Six other species are in the “Near threatened” category, making a total of 11 out of 14 species that are under some level of threat to their existence. There are multiple threats posed to these grazers. They have all been extensively hunted for their meat and hides. The horns of some species have been sought by trophy hunters. These grazers are also under threat from grazing competition from farm animals, especially the domesticated yak. According to the World Wildlife Fund (2019), habitat loss is also extensive in the Asian alpine regions. Over 75% of primeval Himalayan habitat has been destroyed or degraded. Fuelwood and fodder collection have damaged subalpine forests and alpine grasslands. In addition to wild grazers having to compete with domesticated animals for food, extensive livestock grazing in alpine meadows has permanently altered plant community composition.

Fig. 4 The Plateau pika is a keystone species in its habitat. Data from by Smith, A.T., Foggin, J.M. (1999). The plateau pika (*Ochotona curzoniae*) is a keystone species for biodiversity on the Tibetan plateau. *Animal Conservation* 2, 235–240.

In the past 100 years, the population of wild yaks has declined rapidly due to human activities (Table 5). There are four major anthropogenic activities that threaten the long-term survival of wild yaks (Shi et al., 2016). The first is excessive hunting. Poaching, including commercial poaching, has always been regarded as the most serious threat to wild yaks, especially for male yaks. Since the mid-1950s, highway construction has facilitated access of commercial poachers to wild yak's populations, increasing the hunting pressure and the threats to wild yaks. Between 1958 and 1961, a large team hunted wild yaks in the area of Yoniugou and elsewhere in Qinghai Province, China, that killed at least 40,000 mammals. To this day, the populations of wild yaks and other wildlife in these regions have not recovered. The extent of poaching has declined in recent decades. However, increasing numbers of human-wildlife conflicts due to resource competition has increased the extent of retaliatory killing. Owners of domesticated grazers (yak, horse, donkey, sheep, and goats) kill wild yaks that compete with their livestock for grazing access. In addition to causing human-wildlife conflict, competition for forage resources has led to habitat destruction and fragmentation, causing reduced gene flow between populations. Studies have found that wild yaks probably need larger ranges than other wild ungulates, with limited or no human disturbances. Roads are also a major obstacle to wild yak migration.

Bos mutus (Wild yak)

Hemitragus jemlahicus (Himalayan tahr)

Budorcas taxicolor (Takin)

Ovis ammon (Argali)

Naemorhedus griseus (Chinese goral)

Pseudois nayaur (Bharal)

Capra falconeri (Markhor)

Table 5 Estimated numbers of wild yaks in Chinese provinces

Province	Total area (km ²)	Estimated population size
Gansu	454,430	130
Qinghai	721,000	3200–3700
Tibet	1,202,369	7157–8761
Xijiang	1,660,000	10,000

Data from Shi, Q., Guo, Y., Engelhardt, S.C., Weladji, R.B., Zhou, Y., et al. (2016). Endangered wild yak (*Bos grunniens*) in the Tibetan plateau and adjacent regions: Population size, distribution, conservation perspectives and its relation to the domestic subspecies. *Journal for Nature Conservation* **32**, 35–43.

The dwarf blue sheep (*Pseudois nayaur schaeferi*) is a critically endangered subspecies of the blue sheep, found only in China (Upper Yangtze Gorge in west Sichuan and adjacent parts of Tibet and north Yunnan). The population has declined by more than 50% in the last 10 years. Although protected by the Chinese government, this sheep continues to be hunted by poachers. In fact, the hunters themselves report that the numbers of this subspecies had fallen drastically. Previously observed group size ranges of 10–36 animals have dropped to 3–6 animals in recent years.

The Himalayan tahr (*Hemitragus jemlahicus*) lives along the Himalayan range from northwest India through Nepal to Sikkim, and localities along the western Chinese border. This bovine inhabits steep rocky mountain sides, around the treeline and forest edges from 2500 to 4000 m. The species is considered to be declining, and it is assessed as Near Threatened on the IUCN Red List. The tahr is important prey for snow leopard populations in Nepal.

Cervids: Deer, elk, and moose

Numbers of both the alpine musk deer and Himalayan musk deer are declining rapidly because of the demand for their musk—a secretion from the caudal gland of male musk deer. Musk is used in fragrances and perfumes and in Chinese folk medicines. Data on musk purchased by local traditional Chinese medicine companies suggest dramatic declines in Chinese musk deer populations since the 1970s and 1980s. In protected areas of Nepal, musk deer numbers are reportedly increasing, with upwards of 2500 individuals in national parks. Outside of protected areas the species is declining.

Predators (Fig. 6)

Predators of the Asian alpine regions include the family Felidae (cats, lynx, tiger, and snow leopard), Canidae (wolves, foxes, jackals, and dhole), Mustelidae (badgers, weasels, and wolverine), and Ursidae (bears). Nine out of the fifteen species of predators are under some level of threat in Asia, according to the IUCN. As with the large mammals discussed above, habitat loss, over-hunting, and retaliatory killing have taken their toll on predator species' populations. An additional hazard to predators is the decline in numbers of their prey species.

Felidae (cats, lynx, tiger, and snow leopard)

The Chinese mountain cat is a small cat, about the size of the domesticated cat. It lives only in the Chinese provinces of Xinjiang, Qinghai, and Gansu. Its numbers are thought to be less than 10,000 individuals. Ironically, one the main causes of decline for this species is accidental killing through the use of poisons to control rodents. It is also suffering from trapping and hunting for the illegal fur trade. The IUCN lists it as "Vulnerable."

In the Asian highlands there is a subspecies of lynx known as the Tibetan lynx. While numbers of the Tibetan lynx are strong in China (more than 27,000), the species is considered "Vulnerable" further west in Uzbekistan. It is found along the northern slopes of the Himalayas, and has been reported from barren, rocky areas above the tree line, as well as in forested regions.

Pallas's cat is very wide ranging in Asian highlands, from Iran east to the mountains of China. Like the Chinese mountain cat, Pallas's cat is about the size of a domesticated cat. This cat is very secretive in habit. Pictures of Pallas's cat have only been taken within the last decade, through the use of camera trapping surveys. Pallas' cats are ambush hunters that stalk their prey using short vegetation and rocky terrain for cover. They also wait at entrances to burrows and pounce when their inhabitants exit. Pallas' cats prey mainly upon pikas and other small rodents, and birds. Populations of this species have declined because of habitat degradation, decline in prey numbers, and hunting. It is classified as Near Threatened by the IUCN.

The snow leopard is another cat that is rarely seen by people. These large cats are sparsely distributed over the mountainous regions of 12 countries in Central Asia. They take a wide variety of prey (Table 6), but their main prey animals are the large, wild ungulates that live in the snow leopard's range. Chetri et al. (2019) studied snow leopard populations in Nepal. The global snow leopard population size has been estimated between 4678 and 8745 individuals. However, this is only a rough estimate. To date, less than 2% of the global snow leopard distribution range has been sampled systematically, and surveys have often focused on prime habitats. They are extremely elusive and challenging to survey. However, new research, including camera trapping, is starting to indicate there may be more cats than previously thought.

Panthera uncia (Snow leopard)

Gulo gulo (Wolverine)

Otocolobus manul Pallas' cat

Mustela altaica (Mountain weasel)

Lynx lynx isabellinus (Tibetan lynx)

Canis aureus (Golden jackal)

Fig. 6 Photo plate of some of the predators of the Asian alpine regions. The main threats to the snow leopard are poaching, retaliatory killings due to livestock loss, declines in prey species numbers, degradation of habitat due to developmental activities (e.g., mining, dams, roads, railway lines, etc.) and global climate change. Blue sheep, Siberian ibex and Marco Polo sheep provide almost 50%–60% of the biomass consumed by the large carnivores of the Asian highlands, including the snow leopard, wolf, brown bear, and lynx. As discussed above, hunting of these alpine sheep is not only legal in countries such as Mongolia, Kyrgyzstan and Tajikistan, it is actively encouraged as a source of much-needed revenue.

Snow leopard pelts are very valuable, and even though killing snow leopards is illegal in the twelve Asian countries where it lives, this trade persists (Fig. 7). It is almost impossible to enforce the antipoaching laws in the snow leopard's remote mountain habitat. Snow leopard poaching in Russia was recently alleviated in several important areas. This was done through a concerted government effort to remove wire-snare from the landscape, and through the recruitment of former poachers as wildlife rangers in protected areas. Anti-poaching efforts in Tajikistan, Kyrgyzstan, and Kazakhstan have also been strengthened, thus addressing the main underlying threat that led to the drastic decline in numbers in several Central Asian states (Snow Leopard Trust, 2019).

Table 6 Species recorded in snow leopard diet

<i>Common name</i>	<i>Scientific name</i>
<i>Mammals</i>	
Siberian ibex	<i>Capra ibex</i>
Markhor	<i>Capra falconeri</i>
Blue sheep (bharal)	<i>Pseudois nayaur</i>
Himalayan tahr	<i>Hemitragus jemlahicus</i>
Argali wild sheep	<i>Ovis ammon</i>
Ladakh urial	<i>Ovis orientalis</i>
Elk (red deer)	<i>Cephus elaphus</i>
White-lipped deer	<i>Przewalskium albirostris</i>
Siberian roe deer	<i>Capreolus pygargus</i>
Musk deer	<i>Moschus</i> spp.
Moose	<i>Alces alces</i>
Goitered gazelle	<i>Gazella subgutturosa</i>
Wild ass	<i>Equus hemionus</i>
Wild boar	<i>Sus scrofa</i>
Wild camel	<i>Camelus ferus</i>
Himalayan marmot	<i>Marmota himalayana</i>
Altai marmot	<i>Marmota baibacina</i>
Long-tailed marmot	<i>Marmota caudata</i>
Menzbier's marmot	<i>Marmota mensbieri</i>
Red squirrel	<i>Sciurus vulgaris</i>
Tien Shan ground squirrel	<i>Sciurus relictus</i>
Royle's mountain vole	<i>Alticola roylei</i>
Pika	<i>Ochotona</i> spp.
Royle's pika	<i>Ochotona curzoniae</i>
Tolai hare	<i>Lepus tolai</i>
Arctic hare	<i>Lepus timidus</i>
Desert hare	<i>Lepus tibetanus</i>
Woolly hare	<i>Lepus oiostolus</i>
Red fox	<i>Vulpes vulpes</i>
Stone marten	<i>Martes foina</i>
Yellow-throated marten	<i>Martes flavigula</i>
Least weasel	<i>Mustela nivalis</i>
Common palm civet	<i>Paradoxurus hermaphroditus</i>
Eurasian badger	<i>Meles meles</i>
Brown bear	<i>Ursus arctos</i>
<i>Birds</i>	
Snowcock	<i>Tetraogallus</i> spp.
Rock ptarmigan	<i>Lagopus mutus</i>
Chukar	<i>Alectoris chukar</i>
Pheasants	Phasianidae spp.
Pigeons	Columbidae spp.

Data from Mallon, D., Harris, R.B., Wegge, P. (2016). Chapter 4: Snow leopard prey and diet. In: McCarthy, T., Mallon, D. (eds.), *Snow Leopards*, pp. 43–55. Amsterdam: Elsevier.

Canids (*wolves, foxes, jackals, and dhole*)

The Tibetan wolf (*Canis lupus chanco*) is a subspecies of the gray wolf (*Canis lupus*). The Tibetan wolves are distinct from their European and North American counterparts because of the coloration of their fur. Tibetan wolves have been hunted, trapped, and poisoned in the Asian highlands for many decades. Nevertheless, they remain an important predator in alpine ecosystems of the Himalaya and Tibetan Plateau. The efficiency of wolves in taking large prey animals and the increasing levels of encroachment of yaks, goats, sheep and other domesticated ungulates into the alpine means that conflict with livestock herders is inevitable. Wolf predation on livestock is very costly to the herder. For instance, when wolves kill a domesticated yak, the herder suffers a loss of almost \$1000. This may lead to retribution killings, even in countries where the wolf is legally protected, such as Nepal. Wolves that live in wildlife sanctuaries and preserves may receive protection, but as pack sizes increase, small groups wander away from the protected areas. Wolves in this region are listed as critically endangered in IUCN Red List.

Dholes are a kind of wild dog that is a generalist carnivore. Their favorite prey is the wild boar, followed by barking deer, musk deer, blue sheep, goral, and pika (Aryal et al., 2015). Like wolves, dholes have been systematically hunted, trapped, and poisoned throughout their range in the Asian high country, due to their preying on livestock. The IUCN reckons that there are only about 950–2200 dholes today. They fall into the “Endangered” category because of such small numbers. The subspecies known as the Ussuri dhole exists in small, isolated populations in Bhutan, China, India, and Nepal.

Tibetan sand foxes are native to the Ladakh plateau of northern India and to the Tibetan Plateau and adjacent regions of China. They primarily prey on Plateau pikas, and are known to cooperate in pika hunting with brown bears. The bears dig the pikas out of their burrows, and the foxes catch any pikas that manage to elude the bears. This fox has healthy populations, and considered “Least threatened” by the IUCN.

Family mustelidae (*weasels, wolverine, and badgers*)

The mountain or Altai weasel is a small, agile hunter that feeds primarily on pikas and voles. It hunts mainly at night. During the day it seeks shelter in rock crevices and the abandoned burrows of other animals, including the burrows of the animals it has killed. It ranges across Kazakhstan, northern India, Tibet, Mongolia, northeastern China, and southern Siberia. Overgrazing of alpine vegetation by cattle, goats, and sheep has caused declines in the voles and pikas, thereby threatening its food base. Reduction in the weasel’s prey has also been caused by the poisoning of pikas. Herders put out poison for pikas because they compete with livestock for alpine grasses and wild flowers. If a weasel scavenges a poisoned pika carcass, it may be killed by the same poison. Finally, Altai weasel numbers follow the fluctuations of their prey, especially voles, whose numbers vary by a factor of four to five times from year to year.

Multi-Country Conservation Efforts

There are many common threats to the wildlife of the Asian alpine regions, from voles and pikas to wild yaks and snow leopards. The common problems include habitat degradation and loss, the impacts of domesticated ungulates, intrusion into formerly pristine highlands by farms, roads, and fences, impacts from hunting, and trapping and poisoning by poachers and herders. The common denominator here is that human populations of the Asian highlands, which used to be extremely small and based solely on subsistence farming and herding, have grown incredibly. For instance, the human population of the Himalayan region tripled from 11 to 33 million between 1901 and 1981, with the rate of increase accelerating after 1951, and now stands at about 40 million.

Fig. 7 Photo of snow leopard skins being sold in a market in Tibet, used by permission of Brenda Turnidge.

People and wildlife are increasingly coming into contact as human populations grow. This causes conflict as wild animals destroy crops and kill livestock (World Wildlife Fund, 2019). What can be done to protect the remaining wildlife of the region?

One answer is the development of international cooperation among the Asian highland countries. A recent project is called the Kangchenjunga Landscape Conservation and Development Initiative (KLCDI). Stretching along the southern side of Mount Kangchenjunga, India, the Kangchenjunga Landscape (KL) is one of the six transboundary landscapes identified by the International Centre for Integrated Mountain Development (ICIMOD) in the Hindu Kush Himalayan (HKH) region. It covers an area of 25,081 km² and spreads across part of eastern Nepal, Sikkim, and West Bengal of India and the western and south-western parts of Bhutan (Fig. 8). At the heart of this landscape lies Mount Kangchenjunga (8586 m), the third highest peak in the world. This region sustains many of the vital Himalayan rivers and crucial watersheds. With 19 established protected areas, comprising 30% of

Fig. 8 Maps of eastern Nepal, Sikkim, and West Bengal of India and the western and south-western parts of Bhutan, showing the national parks and preserves that make up the Kangchenjunga Wildlife Preserve, showing national park and preserve regions (above) and the regions grazed by domesticated yaks (below). After Kangchenjunga Landscape Conservation and Development Initiative (2019). <http://www.icimod.org/kl>—KLCDI home page website.

the landscape, the KL contains more than 4500 plant species, more than 160 mammal species, 580 bird species, and 600 butterfly species. The landscape serves as a contiguous habitat for many umbrella and charismatic species including snow leopard, takin, Himalayan black bear, and Himalayan musk deer. It is also home to 7.2 million people (KLCDI, 2019).

From 2012 to 2015, the Kangchenjunga Landscape Conservation and Development Initiative (KLCDI) produced a feasibility study of trans-boundary initiatives, conservation and development strategies, and a regional cooperation framework. The implementation phase began in 2016. It has focused on common issues and opportunities such as community-based tourism, value chain developments for livestock and various cash crops, regional cooperation to minimize human wildlife conflict and illegal trade, the development of common research protocols and methods to promote science, policy, and practice interface.

More than 20% of the KL is rangeland, and animal husbandry is deeply embedded in the regional cultures and is the main source of livelihoods for the people of high elevations in Bhutan, Sikkim, and eastern Nepal. One of the most important aspects of the KLCDI has been to find ways to sustain this way of life while preserving or expanding vital wildlife habitat in this region.

The basic precepts of the KLCD initiative face the reality that the people who now live in the Asian highland regions are there to stay, and that they are not going to abandon their traditional way of life, which centers on livestock farming. Thus, the emphasis for wildlife conservation must be to preserve as much of the remaining wilderness as possible while developing ways to diversify the livelihoods of the people who live close by. Such initiatives must involve the cooperation of multiple nations, as the KLCD initiative has done.

The wild mammals of the Asian alpine are a unique, irreplaceable biological resource that deserve our protection. As of this writing, we stand on the cusp of major decisions concerning their conservation. If the peoples of the world, and more particularly the people who live and around the Asian highlands, make determined efforts to preserve this fauna, then it can survive. If conservation issues are ignored, postponed, or weakened because of political pressure, then large numbers of Asian alpine species will very likely become extinct within the next few decades.

Abstract

In South America, “alpine birds” are those bird species inhabiting the High Andes (> 2500 masl). The study of this group has progressed from the inventories and catalogues of expeditions led by 19th-century European naturalists to ecological studies of their distribution, work which has enabled the production of country-specific field guides allowing for continued study by new generations of local researchers and amateurs alike. There are six predominant Andean ecosystems that alpine birds of South America inhabit: *Paramo*, *Puna*, high-Andean wetlands and water bodies, high-Andean forests, human-modified areas and glaciers. Here, we describe high-Andean bird diversity according to its distribution throughout these six ecosystems and discuss threats to bird populations and conservation approaches. Altogether, these habitats host a species-rich group of 945 species, composed of both resident and migratory species, generalists and also highly specialized, endemic birds. Because many are specialized, mountain-top species, adapted to live within narrow elevational ranges and climatic conditions, one of the greatest conservation concerns facing South American alpine birds is the threat posed by climate change. Although upslope migration appears to be a viable strategy for some species, there is also evidence that others, especially many endemic mountaintop species, could become locally extinct as a consequence of global change. The decoupling of species-habitat and other ecological relationships that could arise from altitudinal migration may be particularly serious for highly specialized birds of *Paramos*, *Polylepis* forests, and wetlands. Due to the high vulnerability of South American alpine birds to climate change, it is important to undertake actions for the conservation and restoration of the ecosystems on which they depend as habitat, ranging from legal protection to education.

Introduction

To speak about alpine birds of South America is to speak of the birds of the High Andes. Ranging from Venezuela to Patagonia, the Andes are recognized as the most latitudinally-extensive tropical mountain range in the world (Fig. 1) (Borsdorf and Stadel, 2015) and as one of the most biodiverse areas in the world (Myers et al., 2000). The complex topography, with altitudinal gradients exceeding 6000 m, shapes interactions among biotic, climatic and environmental factors, promotes high rates of speciation, and provides habitat for many species endemic to the Andes (Terborgh and Weske, 1975). Not only is within-site, or alpha, diversity high, but the Andes also has a high turnover of species (beta diversity) and ecosystems along elevational and altitudinal gradients (Borsdorf and Stadel, 2015). As one traverses elevational or latitudinal gradients, restricted-range, sister species are commonly encountered, as they replace each other. For these reasons, as many as 900 bird species can be encountered along some Andean elevation gradients, such as the Manu Road (300–3100 masl), Mayo Valley and Abra Patricia in Peru.

In this chapter, we discuss alpine birds of South America from an ecological perspective applied to conservation. After a brief introduction to the history of these studies, we define these alpine birds according to their relationship to six main high-elevation ecosystems. In each ecosystem, we explore general aspects of the associated bird community, highlighting what we consider the most relevant and interesting information for general knowledge and conservation. Finally, we discuss the conservation concerns of alpine birds of South America in the context of climate change.

History of Alpine Birds of South America

The study of Alpine birds of South America began with the expeditions of European naturalists during the early 19th century. In 1802, German naturalist and explorer Alexander von Humboldt commenced the first expedition, in which he described and collected specimens across much of the northern Andes. His work includes iconic interpretations and illustrations of the pattern of replacement within plant and animal communities along the slopes of Ecuador's Chimborazo volcano. Later, French, Swiss and Polish naturalists collected thousands of bird specimens throughout the High Andes of Chile, Bolivia and Peru although these were not more thoroughly explored until the late 19th century and early 20th century. Thomas Oldfield and Perry O. Simmons, led some of the main expeditions, collecting a large number of specimens throughout the Andes of Ecuador, Peru, Bolivia and Argentina. Likewise, Frank Chapman and Melbourne Armstrong Carriker, Jr. collected and independently described several high-elevation bird species in the Santa Marta region and the three main ranges (Cordillera Occidental, Central and Oriental) of Colombia and the high mountains of Ecuador, Peru and Bolivia. Many of these species are recognized as endemic and highly specialized species to specific ecosystems (e.g., *Anairetes alpinus*) (Fjeldså and Krabbe, 1990). Other ornithologists that improved our knowledge of alpine bird diversity, including John Todd Zimmer (1889–1957), James Bond (1900–89), and Rodolphe Meyer de Schauensee (1901–84) working mainly in Ecuador, Peru and Bolivia.

During the second half of the 20th century and beyond, the most notable advances were made in the new ecological study of species distributions. Around 1969, François Vuilleumier (1938–2017) pioneered the ecological, evolutionary and biogeographical study of alpine birds and elucidated how mountains act as both as biogeographical barriers and as chains of “islands” that shape speciation processes similar to those occurring in archipelagos (Vuilleumier and Monasterio, 1986). At the same time, John Terborgh began intensive studies to understand how biotic, climatic and environmental factors explain high-elevation bird diversity along elevation gradients in Peru (Terborgh, 1977). Nevertheless, expeditions to unexplored high-elevation areas continued, improving our knowledge of distributions, sometimes describing new species, and allowing for the collection and study of bird vocalizations. For example, Maria and Hans-Wilhelm Koepcke described the White-cheeked Cotinga (*Zaratornis stresemanni*), an endemic frugivore and one of the few altitudinal migrants at high elevations. Ted Parker’s new and extensive song collection from along the entire Andes supplemented the knowledge of high-Andean birds. Collectively, this body of work became foundational papers for the understanding of alpine bird ecology worldwide.

An important milestone in the progress of South American Alpine ornithology was the development of field guides for amateur and professional ornithologists. In 1990, John Fjeldså and Niels Krabbe, based on their extensive experience in the High Andes, published the “Birds of the High Andes,” describing ~1100 bird species, including some previously unnamed species together with ~2000 illustrations, and information-rich distribution maps. More recently, the publication of several bird field guides by country, such as the Birds of Venezuela; Birds of Colombia; Birds of Ecuador; Birds of Peru; Birds of Bolivia and Birds of Chile has supported the development of a new generation of Latin American biologists, ecologists and ornithologists interested in the study and conservation of South American Alpine birds and the ecosystems they depend on.

Alpine Birds of South America and Their Ecosystems

For this chapter, we define “alpine bird” as a species that inhabits one or more high-elevation (>2500 masl) mountain ecosystems in South America (Fig. 1). According to the elevational ranges compiled by Quintero and Jetz (2018), 945 bird species (in 385 genera and 61 families) distributed throughout Venezuela, Colombia, Ecuador, Peru, Bolivia, Chile and Argentina, meet this definition (Supplementary Table 1 in the online version at <https://doi.org/10.1016/B978-0-12-409548-9.11806-8>). Because Andean ecosystems are shaped by different climatic regimes and topographic relief (Borsdorf and Stadel, 2015), they are useful biological and ecological units around which to organize our discussion of alpine birds of South America. Therefore, we focus this chapter on alpine bird diversity associated with six main ecosystems: *Paramo*, *Puna*, high-Andean wetlands and water bodies, high-Andean forests, areas modified by human activities, and glaciers. A summary of these species by country and the six ecosystems are included on the Supplementary Table 2 in the online version at <https://doi.org/10.1016/B978-0-12-409548-9.11806-8>.

Paramos

Paramo is a grassland-shrubland ecosystem found between ~3000–5000 masl from Venezuela to northern Peru (Fig. 3) in areas that are humid year-round, with >3000 mm of annual precipitation, and that lack strong seasonality (Rundel et al., 1994). *Paramo* is dominated by tussock grasses (primarily *Festuca* and *Calamagrostis* spp.) and rosette plants and is often distinguished by abundant stemmed rosette plants of *Espeletia* spp. (*frailejones*), which are missing from the central and southern Andes (Balslev and Luteyn, 1992). In their middle elevations, *Paramos* are also characterized by their deep, organic-rich humic or volcanic soils that hold large amounts of water (Balslev and Luteyn, 1992).

Although a number of studies have described avifauna associated with *Paramo*, the total number of species remains uncertain. Prior studies have reported anywhere from 32 to 40 species belonging to 15 families and 8 orders in Ecuador (Koenen and Gale, 2000), to 60 bird species, including 29 *Paramo* specialists, in Venezuela, Colombia and Ecuador, to 79 resident species and 67 occasional visitors or migrants in Venezuela (Diaz et al., 1997). At the higher end of species richness, Chaves and Arango (1998) reported 129 bird species, from 84 genera and 31 families, in the Colombian *Paramos*, whereas Krabbe et al. (2006) reported 155 bird species from Colombia.

Both resident and migratory species use *Paramo*. About 30 migratory species, including Lesser Yellowlegs (*Tringa flavipes*), Least Sandpiper (*Calidris minutilla*), and Killdeer (*Charadrius vociferus*), use the Andes as a migratory corridor and stopover in *Paramos* to rest or replenish fuel reserves. A wide range of resident species that reflect various foraging strategies and adaptations to high-elevation environments occur in *Paramo* (Diaz et al., 1997), with ground insectivores and hummingbirds being most numerous and distinct. The coloration and behavior of many *Paramo* birds reflects their environment and enables camouflage and avoidance of predators (e.g., ground nesting, skulking and obscure movements) (Fjeldså and Krabbe, 1990). Common residents include the *Paramo* Pipit (*Anthus bogotensis*); *Paramo* Tapaculo (*Scytalopus opacus*); *Paramo* Seedeater (*Catamenia homochroa*); Chestnut-winged Cinclodes (*Cinclodes albidiventris*), and Ash-colored Tapaculo (*Myornis senilis*), among others.

Hummingbirds have developed specific adaptations to exploit the *Paramo* resources. Snow (1983) observed that hummingbirds specialize on different species of *Frailejon* (*Espeletia* spp.) by using their unusually short beaks and long legs to perch and feed on the nectar and on insects that are often trapped in the water that accumulates in these plants. Hummingbirds also have respiratory adaptations that allow them to fly in hypoxic conditions (i.e., at high elevations) (Altshuler and Dudley, 2006). Many of these species are endemic to specific mountain ranges while others migrate seasonally to lower elevations during the dry season. Some endemic species include: the Ecuadorian Hillstar (*Oreotrochilus chimborazo*), Buffy Helmetcrest (*Oxygogon stubelii*),

Blue-bearded Helmetcrest (*Oxygogon cyanoaemus*), White-bearded Helmetcrest (*Oxygogon lindenii*), and Green-bearded Helmetcrest (*Oxygogon guerini*), whereas the Purple-backed Thornbill (*Ramphomicron microhynchum*), and Bronze-tailed Thornbill (*Chalcostigma heteropogon*) make seasonal altitudinal movements (Fig. 4). Resident hummingbirds in the *Paramo* include some widespread species like the Giant Hummingbird (*Patagona gigas*), Great Sapphirewing (*Pterophanes cyanopterus*), Black-tailed Trainbearer (*Lesbia victoriae*), and Green-tailed Trainbearer (*Lesbia nuna*). Despite being a relatively well-studied and charismatic group, new hummingbird species continue to be discovered. The Blue-throated Hillstar (*Oreotrochilus cyanoaemus*), for example, was recently described in a remote *Paramo* area of the southwestern Andes of Ecuador and listed as critically threatened, due to its restricted distribution, small population (<750 individuals), and vulnerability to ongoing threats (Sornoza-Molina et al., 2018).

Puna

Puna ecosystems are another grassland-shrubland ecosystem found between ~3000–5000 masl from Northern Peru to Chile and Argentina (Fig. 5). *Puna* is distinguished from *Paramo* by climatic regime and floristic composition (Rundel et al., 1994). *Puna* is found in areas with <2000 mm of annual precipitation and seasonally arid periods 3–6 months of the year (Troll, 1965). It is dominated by grasses and cushion plants (Rundel et al., 1994). Three types of *Puna* systems are defined by rainfall and seasonality: moist, dry, and desert (Troll, 1965; Baied and Wheeler, 1993).

Moist *Puna* covers most of the Peruvian and Bolivian high Andes, typically between 3700 and 5000 masl (Fig. 5) in areas with 400–2000 mm of annual precipitation and annual temperatures of 5–7°C. Humidity gradients along the Andes change with latitude, as do the distributions of *Puna* birds. In particular, the degree of distinction between the eastern and western slopes of the Andes increases with latitude, and species associated with more arid conditions are most likely to occur along the western slopes in the central and southern Andes (Fjeldsø and Krabbe, 1990). Some species may have extensive latitudinal ranges but extremely restricted elevational distributions. The moist *Puna* areas are mainly dominated by *Ichu* (*Stipa ichu*), other tussock grasses such as *Festuca dolichophylla* and *Calamagrostis* spp., with interspersed wetlands and stands of *Polylepis* trees or *Puya raimondii*. The complex topography is often mirrored by patterns of endemism and richness among the birds. Among the most representative genera are the Canasteros (*Asthenes* spp.), Ground-Tyrant (*Muscisaxicola* spp.), Miners (*Geositta* spp.) and Earthcreepers (*Upucerthia* spp.) (Fjeldsø and Irestedt, 2009) (Fig. 6).

The dry and saline *Puna* is located further south along highland plateaus between 3500 and 5000 masl in Chile, Bolivia and Argentina (Fig. 5). These areas receive 100–400 mm of annual precipitation and often have a large number of salt bodies locally called “salares” and areas dominated by Tola shrubs (*Parastrephia quadrangularis*) and the tussock grasslands of *Festuca orthophylla*. Birdlife is generally less diverse and numerous than moist *Puna* and common residents include Puna Tinamou (*Tinamotis pentlandii*), Andean Goose (*Oressochen melanopterus*), Puna Miner (*Geositta punensis*), Puna Canastero (*Asthenes sclateri*), Puna Ground-Tyrant (*Muscisaxicola juninensis*), Yellow-Finch Puna (*Sicalis lutea*).

Finally, the *Puna* desert, which is characterized by the near total lack of precipitation, extends to the southernmost zone of *Puna* distribution (Fig. 5). Vegetation communities are sparse and xerophytic, such as the cushion plants Yareta (*Azorella compacta*), Tola (*Baccharis incarum*) and Cardón de la Puna (*Echinopsis atacamensis*). There are few bird species here, with only ~20 species recorded, including five specialists. These are the Lesser Rhea (*Rhea pennata*), Tawny-throated Dotterel (*Oreopholus ruficollis*), Least Seedsnipe (*Thinocorus rumicivorus*), Gray-bellied Shrike-Tyrant (*Agriornis micropterus*), and Spot-billed Ground-Tyrant (*Muscisaxicola maculirostris*) (Vuilleumier, 1997).

High-Andean Wetlands

High-Andean wetlands include a rich assortment of peatlands, swamps, lagoons and lakes that are fed by rain and glaciers. Peatlands, peat bogs or *bofedales*, as they are locally called, are the bulk of high-Andean wetlands and are characterized by fertile and very moist soils that retain water year-round, and support cushion plants (*Distichia* spp., *Oxychloe* spp., *Plantago* spp.) that act as sponges for water storage and provide “oases” for migratory and resident birds (Weller, 1999; Fig. 7). In Peru 98 bird species—including 38 specialists—were recorded in Andean peatlands (Gibbons, 2012), although lower levels of species richness were reported for Bolivia (16 species, Naoki et al., 2014), Peru (34 species, Tellería et al., 2006), and Argentina (60 bird, Josens et al., 2017). That said, despite not being especially species rich, peatlands and other high-Andean wetlands support distinctive bird communities that include the Black-faced Ibis (*Theristicus melanopis*), Puna Ibis (*Plegadis ridgwayi*), Andean Negrito (*Lessonia oreas*), Gray-breasted Seedsnipe (*Thinocorus orbignyianus*), and Andean Lapwing (*Vanellus resplendens*) as well as many ducks (Anatidae), coots and rails (Rallidae) (Fig. 8).

One alarming projection is that 75% of Andean peatlands, systems that only comprise approximately 5% of the land in the High Andes, may disappear with climate change (Gibbons, 2012). As a consequence, some birds highly adapted to peatland habitats could become extinct (IUCN; BirdLife International, 2018). The White-bellied Cinclodes (*Cinclodes palliatus*) is one of these. This species is critically endangered (CR) (BirdLife International, 2018) given that its population of <250 individuals is restricted to elevations between 4400 and 5000 masl of the central Andes of Peru. Populations of this species are decreasing primarily because of peat extraction, overgrazing, mining, and water extraction for agriculture (BirdLife International, 2018). The Diademed Sandpiper-Plover (*Phegornis mitchellii*) is another species considered by the IUCN Red List as near-threatened (BirdLife International, 2018).

Lakes and lagoons are another important habitat for alpine birds (Fjelds , 1985). The Totora reed (*Schoenoplectus californicus*), in particular, provides food, refuge and breeding habitat for many birds including the Chilean Flamingo (*Phoenicopterus chilensis*), Andean Flamingo (*Phoenicoparrus andinus*), Andean Duck (*Oxyura ferruginea*), Yellow-billed Pintail (*Anas georgica*), Giant Coot (*Fulica gigantea*), and Slate-colored Coot (*Fulica ardesiaca*). One of the most interesting, but endangered, groups inhabiting wetlands, are grebes (Podicipedidae), which include several flightless species endemic to single lakes or regions. Examples include the Jun n Grebe (*Podiceps taczanowskii*) restricted to the Jun n Lake in Peru (4082.7 masl), the Titicaca Grebe (*Rollandia microptera*) restricted to Lake Titicaca between Peru and Bolivia (3812 masl), and the extinct Colombian Grebe (*Podiceps andinus*) that was recorded for the last time in the wetlands of Bogota (2600 masl) in 1977 (BirdLife International, 2018).

High-Elevation Forests

Although the classic definition of “alpine zones” specifies areas above treeline, the High Andes hosts trees above 2500 masl and even up to 5100 masl for some small patches of forest dominated by *Polylepis* trees (Purcell et al., 2004). In the northern and eastern slopes of the Central Andes, upper montane or cloud forest comprises areas of continuous forest cover up to 3000 masl, with mixed-species forest cover, epiphyte-rich canopies, and underbrush providing complex habitat for many bird species, some of which are not high-elevation specialists. In the southern regions and western slopes of the Central Andes, patches are sparser and are comprised of trees such as *Alnus acuminata*, *Escallonia* spp., and *Buddleja* spp. However, across the Andes above 3000 masl, it is the small forest islands comprised of *Polylepis* trees that contribute most uniquely to bird diversity in the alpine zone, providing important habitat for endemic, specialized, and vulnerable species.

Polylepis forest

Forests dominated by trees and shrubs of the genus *Polylepis* (Rosacea) are restricted to the High Andes and Cordoba Mountains of Argentina (Kessler and Schmidt-Lebuhn, 2006) (Fig. 2E–F; Fig. 9). *Polylepis* forest represents the upper elevational extent of forest in the world (~5100 m) (Purcell et al., 2004) and are a recognized center of avian diversity and endemism (Fjelds , 2002). Across the Andes, *Polylepis* forests are regularly used by 214 bird species, which include 31 endemic species, 27 IUCN red-listed species, and 23 specialists (Sevillano-R os et al., 2018) (Fig. 10). Not surprisingly, the fragmented distribution of *Polylepis* forests at local, regional and continental scales shapes the distribution of many specialized *Polylepis* birds, which are often restricted in population size and geographic extent (Lloyd, 2008; Sevillano-R os and Rodewald, 2017). Consequently, many birds associated with *Polylepis* are globally threatened (BirdLife International, 2018) and require deliberate conservation (Fuentealba and Sevillano, 2016).

In the Northern Andes, *Polylepis* forms small woodland patches above 3200 masl within the *Paramos* (Fandi o and Caro, 2009). Vegetative diversity is high in these humid zones, with species like *Frailejones* (*Espeletia* spp., *Coespeletia* spp.) and shrubs such as *Hypericum laricifolium*, *Weinmannia*, *Oreopanax*, *Myrsine*, *Miconia*, *Ageratina*, *Ribes*, *Monticalia*, *Tibouchina*, *Hesperomeles*, *Hypericum*, *Berberis*, and *Gynoxys baccharoides* (Fandi o and Caro, 2009). As an interesting contrast, the northern Andes region lacks avian

Fig. 2 Bird communities of six main high-Andean ecosystems covered here. The *Paramo*, restricted to the northern Andes (A); the *Puna* covering the major part of central Andes (B); lakes, lagoons (C) and wetlands (*bofedales* in Spanish) (D); high-elevation forest dominated by *Polylepis* trees (E–F); human-modified ecosystems (G) and glaciers, usually above 5000 m (B, C, H). specialists on *Polylepis* and most bird species in this habitat are also found in humid montane forests (Valderrama and Verhelst, 2009; Sevillano-Ríos et al., 2018). Nevertheless, some species of high conservation value, such as the globally-threatened Dusky Starfrontlet (*Coeligena orina*) (CR), depend of these forests (BirdLife International, 2018).

The northern and middle Central Andes contain the highest number of birds specialized on *Polylepis* within roughly three elevational zones. At lower elevations (~2500 masl), *Polylepis* borders cloud forest and, as such, shares many of the same species from groups like tanagers, flowerpiercers (Thraupidae) and hummingbirds, and even a few *Polylepis* specialists such as the Giant Conebill (*Conirostrum binghami*) (Vuilleumier, 1984). At intermediate elevations (3400–3800 masl), *Polylepis* starts to dominate mixed-forest stands of *Gynoxys*, *Buddleja*, *Baccharis*, *Senecio* and *Berberis* (Fjeldsâ, 1992; Kessler, 2006,) and bird communities become notably more diverse (Lloyd, 2008; Sevillano-Ríos and Rodewald, 2017). A recent study from *Polylepis* forests in Cordillera Blanca in the northern central Andes reported ~30–40 bird species, including a mix of generalists and specialists, such as the Tit-like Dacnis (*Xenodacnis parina*), Line-cheeked Spinetail (*Cranioleuca antisensis*); Baron's Spinetail (*C. baroni*) and Stripe-headed Antpitta (*Grallaria andicolus*) (Sevillano-Ríos and Rodewald, 2017; Fig. 11). At higher elevations (3800–4700 masl) the environments are increasingly cold but wet, with *Polylepis* forest forming islands on the moist *Puna* landscapes (Kessler, 2006). Incredibly, this is where the endemic and highly specialized Andean bird diversity peaks (Lloyd, 2008; Sevillano-Ríos and Rodewald, 2017; Sevillano-Ríos et al., 2018). Some of the most representative bird species include the Giant Conebill (*Conirostrum binghami*), Royal Cinclodes (*Cinclodes aricomae*), Tawny Tit-Spinetail (*Leptasthenura yanacensis*), White-browed Tit-Spinetail (*Leptasthenura xenothorax*), and the White-cheeked Cotinga (*Zaratornis stresemanni*) (Fig. 11).

Fig. 4 Hummingbirds associated to the *Paramo*: (A) Ecuadorian Hillstar (*Oreotrochilus chimborazo*); (B) Sparkling Violetear (*Colibri coruscans*); (C) Black-tailed Trainbearer (*Lesbia victoriae*); (D) Blue-mantled Thornbill (*Chalcostigma stanleyi*); (E) Shining Sunbeam (*Aglæactis cupripennis*); (F) Giant Hummingbird (*Patagona gigas*); (G) Buffy Helmetcrest (*Oxypogon stubelii*); (H) Purple-backed Thornbill (*Ramphomicron microrhynchum*). Photos: Rubi Shapiro (A); Steven Sevillano-Rios (B–F), Juan José Arango (G), Andrés García Ávila (H).

Finally, the southern Central Andes are increasingly cold and dry, with *Polylepis* forest forming islands on the dry and desert *Puna* landscapes at very high elevations (3800–5100 masl). Here, along with a decreasing degree of bird diversity, almost no *Polylepis* bird specialists are found. Yet, one endemic species, the Olrog's Cinclodes (*Cinclodes olrogi*), is associated with *Polylepis* at these latitudes (BirdLife International, 2018).

Human-Modified Areas

Human-modified or anthropogenic areas include cities, towns, crop fields, forest plantations and other areas modified by humans since the Andes were settled approximately 10,000 years ago (Rademaker et al., 2014). As is typical for these landscapes, certain bird species tolerate disturbances better than others and several have adapted quite well to living in human environments (Slabbekoorn and Peet, 2003). In many cases, they are species that modify their nesting behavior to use manmade materials and may feed on crops or even from the waste that is generated by man. In general, these are generalist and cosmopolitan species that are found throughout the Andes or are cosmopolitan throughout the Americas and benefit from the disturbances of the landscape. The city of Bogotá (2600 masl), for example, is one of the largest cities in the Andes and according to eBird, around 250 species have been registered within the city (eBird records in October 2018). Many of these observations have been made on the Monserrate hill (146 species), the Córdoba wetland (162 species) and La Florida Park (290 species). Quito (2850 masl), another large Andean city, has around 220 bird species while around 200 species were recorded in the city of Cuzco. On the other hand, crop fields and plantations of introduced trees like *Eucalyptus*, have strongly modified the Andean landscape and nowadays many bird species inhabit them. Some of the most common birds include the Rufous-collared Sparrow (*Zonotrichia capensis*), Chiguanco Thrush (*Turdus chiguanco*), Eared Dove (*Zenaida auriculata*), House Wren (*Troglodytes aedon*), Sparkling Violetear (*Colibri coruscans*), among many others (Fig. 12).

Glaciers

The lower limit of glaciers in the Andes occurs at approximately 5000 masl, and this represents the upper limit of the distribution of many bird species. However, recent observations (e.g., Hardy and Hardy, 2008; Hardy et al., 2018), indicate that in fact, some bird species can nest and feed directly on glaciers. Among these species are the White-winged Diuca-Finch (*Idioparus specularis*), Taczanowski's Ground-Tyrant (*Muscisaxicola griseus*), White-fronted Ground-Tyrant (*Muscisaxicola albifrons*), Plumbeous Sierra Finch (*Geospizopsis unicolor*), Rufous-bellied Seedsnipe (*Attagis gayi*), Gray-breasted Seedsnipe (*Thinocorus orbignyianus*), and some hummingbirds such as the Olivaceous Thornbill (*Chalcostigma olivaceum*).

The White-winged Diuca-Finch is the only bird species known to actively nest in the high Andean glaciers up to ~5400 masl (Hardy and Hardy, 2008; Hardy et al., 2018). In 2005, during a scientific expedition to the Quelccaya glacier, in Cuzco, Peru, Hardy and Hardy (2008) documented the first White-winged Diuca-Finch nest at these elevations. Subsequent observations from the

Quelccaya glacier and the Vallunaraju mountain in Cordillera Blanca by [INAIGEM \(2017\)](#) provide further evidence of this behavior, which has been speculated to occur in many other glaciers along the Andes ([Hardy and Hardy, 2008](#)). More recently, [Hardy et al. \(2018\)](#) reported the results of a decade of study of the White-winged Diuca-Finch nesting biology in glaciers, suggesting that this species could be an obligate glacier-nester. Moreover, their results were also documented by a BBC documentary available online (see extra sources).

The Taczanowski's and the White-fronted Ground-Tyrants are two species that normally inhabit open areas of the *Puna* ecosystem during the day but seem to fly back to small ice-caves in the interior of the glaciers for roosting and spend the night there (Hardy et al., 2018). Moreover, recent observations (Hardy et al., 2018; unpublished data, Autoridad Nacional del Agua, Peru), have discovered them feeding on the glaciers, specifically feeding on insects that were trapped in small holes with a black matter called cryoconites. The same behavior has been recorded for the Olivaceous Thornbill (per. Obs., S. Sevillano-Rios.) in the Pastoruri glacier at 5200 m in Cordillera Blanca and according to Hardy et al., 2018, many more species could be depending of glaciers as an important habitat. Although the number of observations is still limited to anecdotal records, they open the possibility to develop serious studies on understanding why and how alpine birds use glaciers and if some would adapt to live at high elevations under future climate conditions when Andean glaciers disappear.

Vulnerability to Climate Change and Conservation

One of the greatest concerns arising from future climate scenarios is the eventual extinction of many species of flora and fauna, with those restricted to mountain ecosystems, like the high Andes, among the most vulnerable (Şekercioglu et al., 2012). Species will exhibit three alternative responses to climate change: 1) migrate to newly suitable habitat, 2) adapt in situ, or 3) go extinct (Habary et al., 2017). For high-Andean species, there are several reasons to be concerned about their capacity to migrate or adapt in response

to climate change. Many are adapted to live within very narrow climatic ranges with little temporal variability and, due to the complex Andean topography, these species have restricted ranges, low dispersal capabilities and small populations. These characteristics may make movement or in situ adaptation of such species slow, increasing their risk of extinction in the face of rapid climate change; species that do not move to other places or adapt fast enough to keep up with environmental and climatic changes are predicted to become extinct in the near future (Şekercioğlu et al., 2012).

Different species of flora and fauna have successfully moved upslope as a result of the global increase in temperature (see Parmesan and Yohe, 2003; Chen et al., 2011). However, the few studies that have examined upslope movement of Andean birds suggest that such migration may be slow and may not be a viable response for all species. A comparative study developed in Cerros del Cirá in Peru found that although climate change is certainly pushing bird species to modify their upper limit, 55 bird species moved an average of 49 m in a period of 41 years, far below the predicted migration distance (152 m) that would be required to keep up with predicted increase in temperature ($\sim 0.79^{\circ}\text{C}$) (Forero-Medina et al., 2011). More recently, Freeman et al. (2018) showed that after 32 years, the ranges of many mountain bird species in Cerro Pantiacolla, Peru, have shrunk, or their population sizes have decreased. Furthermore, they also found that many mountaintop species have already disappeared in response to climate change (Freeman et al., 2018). Therefore, although upslope migration is occurring and could perhaps be a viable strategy for some species, many mountaintop species may become extinct as a consequence of global change.

One implication of modifying species limits is that species-habitat relationships could also drastically change. For example, because it could take much longer for an entire plant community or ecosystem to migrate the same distance upslope than it does for animal species, this disconnect could generate a lack of suitable habitat at these new climatically suitable elevations. Consequently, this could cause a decoupling of ecological relationships, exacerbating mountain-top extinctions (Colwell et al., 2008). Moreover, modifying species limits could also modify interspecific relationships such as mutualism, competition, or predation. For example, the upslope migration of more competitive, generalist bird species could cause the displacement of subordinate species currently well-adapted to higher elevations; this appears to be the case in Cerro Pantiacolla (Freeman et al., 2018). This could likewise affect many endemic birds specialized to the *Paramos*, the *Polylepis* forests, peatlands or lakes (Freeman et al., 2018; Sevilano-Ríos et al., 2018).

Due to the high vulnerability of South American alpine birds to climate change, we believe that it is important to initiate actions for the conservation and restoration of the ecosystems on which they depend as habitat. Specifically, the following actions should be undertaken: 1) identify and legally protect a large number of priority areas, involving local human populations, together with NGOs, government agencies, and the academy, in the conservation and restoration process; 2) prioritize conservation and restoration of *Paramos*, *Puna*, forests, peatlands, lakes and lagoons located at the headwaters of watersheds because they are highly important and the most vulnerable to climate change; 3) avoid unnecessary destruction of biodiversity by reducing the levels of fire, logging, overgrazing and livestock on these areas (Morales et al., 2018). Instead, the development of more sustainable economic activities (e.g., ecotourism, agroforestry) should be encouraged; finally, 4) educate the public, including local people, visitors and students, but especially policy makers, ministry advisors and politicians who can help determine the effectiveness of the different conservation and restoration actions along the Andes.

Abstract

Africa's alpine biome, the Afroalpine, extends between the treeline and the permanent snow line. The number of bird taxa recorded in the Afroalpine is relatively small, particularly in relation to the speciose subjacent Afromontane. By and large, the avifauna of the Afroalpine represents a greatly impoverished Afromontane community as opposed to its own distinct community, although a few taxa are more regularly encountered than others, including a small number of endemics. Although a limited number of 47 bird taxa populates the alpine belt, there are substantial differences in taxonomic composition between the Ethiopian highlands and the East African mountains. Depending on the strength of their association with the biome, these birds can be assigned to four groups: (1) obligate biome-confined breeding residents, (2) regular biome-affiliated residents, (3) facultative biome-affiliated residents, (4) opportunistic residents and visitors. Among the Afroalpine avifauna, there are interesting ecological aggregations of taxa that have been observed exploiting special food resources. Birds of prey form regionally speciose communities, as do seedeaters among the passerines. However, further research is needed to discern the spatial and temporal patterns of occurrence of Afroalpine birds and the biotic and abiotic triggers shaping their temporal and spatial distribution. We suggest systematic bird monitoring activities and a focus on biological key aspects (feeding, breeding, temporal and spatial movements) and on the effects of climate change.

Introduction

From the viewpoint of an ornithologist, the barren landscapes of high-elevation mountains can be fascinating. The alpine areas of African mountains offer an attractive, yet challenging setting for the observation of relatively species-poor communities. Accordingly, the number of systematic studies of the avifauna of the Afroalpine is low and long-term approaches usually only consider the more speciose biomes at lower elevations.

While it is unsurprising that species diversity in alpine regions around the globe is low, one might expect a more unique African alpine avifauna, considering the continent's species-rich birdlife. In fact, most of the birds found in these realms are not entirely confined to the alpine habitats of Africa's high-altitudinal belt but have strong links to the subjacent Afromontane, which harbors much more diverse avian communities. In the following, we compile the scattered information on African alpine birdlife, analyze underlying patterns of occurrences and discuss challenges for future research.

The African Alpine Biome

Geographic Delimitation

The Afroalpine biome covers only a small fraction of the African continent. Here, we define the Afroalpine as the high mountains of Sub-Saharan Africa, excluding the biogeographically distinct and much lower South-African mountains. As only the highest

elevations above the treeline are considered true alpine habitats, their geographic distribution is limited to a few prominent mountain ranges. By and large, these include the Ethiopian highlands, Mt. Kilimanjaro, Mt. Meru, Mt. Kenya, Mt. Elgon, Mt. Karisimbi, the Rwenzori Mts and Mt. Cameroon. However, the latter is also excluded from our considerations because its high-elevation ranges are mainly covered by montane grasslands constituting a different biome than that of the Afroalpine in the strict sense.

Characteristics

In a simplified ecological definition, the alpine biome as defined here is a high-elevation zone having low temperatures, a short growing season and low-nutrient soils that inhibit tree growth (Fig. 1). Following this definition, the alpine biome extends in variable breadth between the treeline and the permanent snow line, that is, above the montane and below the nival zone.

As with many other mountain regions in the world, a strict elevational delimitation of the Afroalpine is impossible. Treelines vary depending on exposure, slope inclination, solar radiation and other associated abiotic factors such as soil temperature and humidity, creating differences even within short distances on one mountain side (e.g., Hedberg, 1955; Coe, 1967; Uhlig, 1990; Busmann, 2006). During the last several million years, the position of the treeline in Africa has risen and fallen in connection with glaciation and deglaciation events. In East African mountains, the treeline has moved nearly 1000 m uphill since the end of the last glacial maximum, 15,000 years ago (Odada and Olago, 2005), likely influencing distribution and speciation patterns of birds (Moreau, 1966). Many authors include the Ericaceous belt in the Afroalpine despite local tree-like growth of some of these species (Walter and Breckle, 1984), while others do not (e.g., Hedberg, 1955; Coe, 1967; Wesche, 2002). As a consequence, the lower limits of the alpine zones are geographically variable and differ depending on conceptual conventions. Similarly, high-elevation grasslands are sometimes considered part of the Afroalpine as well: the biome is then regarded to consist of two sub-biomes, mountaintop grasslands/shrublands and moorlands (e.g., Dorst and Vuilleumier, 1986; Burgess et al., 2004). Again, here we restrict the Afroalpine only to the tundra-like habitats which largely correspond to the aforementioned “moorland” zone of Moreau (1966). However, this is not identical to the “Ericaceous moorland” zone of Coe (1967). This incongruence also causes different estimates of the extent of the Afroalpine, which is between 6000 km² (Dorst and Vuilleumier, 1986) and 50,700 km² (Burgess et al., 2004), depending on the respective delimitation. These regionally changing boundaries also define the upper limits of agricultural use (“agro-ecological belts”). The uppermost, infertile, zone (called “Werch” or “High Wurch” in Ethiopia) would be situated in the Afroalpine as defined here (Kingdon, 1990; Ritler, 2017).

There are characteristic climatic conditions in the Afroalpine, often including year-round nightly frosts and, during the dry season, warm sunshine by day that favors a characteristic high-elevation vegetation (Moreau, 1966; Brown et al., 1982). Besides sharing low primary productivity, biomass and species number between the arctic tundra and the Afroalpine (Müller, 1981; Lomolino et al., 2010), the atmospheric pressure of the relatively dry air of the Afroalpine is lower, while the insolation is higher, combined with a strongly latitude-correlated photoperiod in the high-elevation alpine biome (Cloudsley-Thompson, 1975). Water resources in Afroalpine regions may depend less on rainfall and more on mist (Walter and Breckle, 1984), and the characteristically low water availability during seasonal dryness clearly sets this biome apart from arctic tundra. Thus, the term “tundra,” maintained for historical reasons because of superficial morphological similarities, should only be applied to the lowland tundra proper of Northern latitudes, while the high-mountain landscapes of the African tropics should be termed “Afroalpine.” The term “páramo,”

Fig. 1 Afroalpine, tundra-like landscape (Bale Mts, Sanetti Plateau Ethiopia). Photo: T. Pröhl.

suggested as a global name for all tropical biota above the treeline (Monasterio and Vuilleumier, 1986) apparently has not gained wide acceptance.

Habitats

Locally different combinations of mountain relief and inclination, annual temperature profile and exposure, and bedrock type cause patchwork distributions of Afroalpine soil and vegetation. It is therefore obvious that habitats are not evenly distributed and that local environmental conditions shape the temporal appearance of habitats and the composition of its associated fauna (e.g., Coe, 1967; White, 1983).

Considering birdlife, there are characteristic habitats of the Afroalpine that are relevant for the occurrence of different taxa. The seasonal availability of water greatly affects the appearance of Afroalpine landscapes. Depending on regional rainfall patterns, moorlands, streams, and even small water bodies (tarns) are present during some periods (Fig. 2). They attract birds such as ducks, waders and cranes (cf. Table 1) to breed in the area. This temporary water supply also provides the basis for food resources including plant matter, nectar, insects and small mammals, from which birds, in particular songbirds and raptors, benefit. Other important habitat features that are present year-round are cliffs, rocky slopes and exposed rocks (Fig. 3). These are not only lookout perches and sources for invertebrate bird food but also provide shelter for nest building. Such rocky elements are often interspersed with varying low shrubby or grassy vegetation, causing small-scale habitat mosaic structures.

Finally, locally-specific interactions of abiotic landscape features, seasonally changing environmental conditions and the resulting biotic responses, lead to temporally different occurrences of bird communities in different geographical parts of the Afroalpine. Triggered by the changing availability of food resources and, to a lesser degree, of breeding opportunities, numerous bird taxa are absent from the area in periods of relative dryness. This is an important temporal aspect of Afroalpine bird communities and explains why these are not particularly species-rich and seasonally dynamic.

The Afroalpine Birdlife

Delimitation of Afroalpine Avifauna

The complexity of delimitating the Afroalpine might also be extended to the circumscription of associated bird communities. The inconsistent and instable climatic conditions of alpine habitats cause mosaic-like animal distribution patterns (Müller, 1981), which also holds true for Afroalpine birds (Moreau, 1966; Monasterio and Vuilleumier, 1986). Despite the fact that African mountains do harbor many bird taxa and among them often endemics with narrow elevational ranges, the wealth of these taxa is not exclusively confined to the Afroalpine. To classify these high mountain bird communities, the term “non-forest bird fauna” has also been used (Moreau, 1966; Monasterio and Vuilleumier, 1986). However, no formal distinction between the Afromontane and the Afroalpine has been agreed in this context. Moreover, the characteristic patchy distribution patterns of African mountain bird populations mainly reflect their predominantly Afromontane ranges. This might also have been the reason why the Afroalpine

Fig. 2 Moorlands, streams, and small water bodies (tarns) are at least seasonally present in the Afroalpine (Bale Mts, Sanetti Plateau Ethiopia). They provide food resources for many bird species and attract breeding by some of them. Photo: T. Pröhl.

Table 1 Important bird taxa found in the Afroalpine and their respective affiliation to the biome.

Group	Ethiopian highlands	East African mountains
1—Obligate biome-confined breeding residents	Ruddy Shelduck <i>Tadorna ferruginea</i> ^{a,b} Golden Eagle <i>Aquila chrysaetos</i> ^{a,b} Red-billed Chough <i>Pyrrhocorax pyrrhocorax</i> ^{a,b}	None
2—Regular biome-affiliated residents	Thekla Lark <i>Galerida theklae</i> (ssp. <i>huei</i>) ^b Brown Warbler <i>Sylvia lugens</i> (ssp. <i>griseiventris</i>) ^b Ankober Serin <i>Crithagra ankoberensis</i> ^b	None

Data compiled from personal observations and from Dorst, J. and Vuilleumier, F. (1986). Convergences in bird communities at high altitudes in the tropics (especially the Andes and Africa) and at temperate latitudes (Tibet). In: Vuilleumier, F. and Monasterio, M. (eds.) *High altitude tropical biogeography*, pp. 120–149. New York and Oxford: Oxford University Press. Taxonomy follows del Hoyo and Collar (2014, 2016).

avifauna has only rarely been given enough attention as a separate community. Instead, alpine regions of Africa were considered merely the topmost sub-region of a larger montane zone that extends the lowland zone uphill. Indeed, regular occurrences of certain birds in the Afroalpine are predominantly offshoots of more extensive montane ranges of the same species (Moreau, 1966). Consequently, there is no unique high-elevation avifauna characterizing the Afroalpine.

Birds of the Afroalpine

Here we present a preliminary compilation of avian taxa that have been recorded in the Afroalpine (Table 1). As of yet, our geographic comparisons and conclusions are provisional due to the relatively few studies that systematically assess Afroalpine bird-life, making bird faunal comparisons difficult (Moreau, 1966; Dowsett, 1986). Especially on a smaller geographic scale, information

Fig. 3 Important habitat features of the Afroalpine are cliffs, rocky slopes and exposed rocks, serving as lookout perches for birds and providing shelter for nest building (Bale Mts, Sanetti Plateau Ethiopia). Photo: T. Pröhl.

on regional or local differences between alpine bird communities is still fragmentary. Only a limited number of 47 bird taxa is more or less bound to the alpine belt (**Table 1**). Moreover, there are pronounced differences in occurrences between the Ethiopian highlands and the East African mountains. Depending on the strength of their association with the biome, these birds can be assigned to four groups:

Group 1—Obligate biome-confined breeding residents. These birds exclusively inhabit the Afromontane.

Group 2—Regular biome-affiliated residents. These birds predominantly inhabit the Afromontane.

Group 3—Facultative biome-affiliated residents. These birds have a substantial amount of their ranges in the Afromontane.

Group 4—Opportunistic residents and visitors. These birds are regularly, though opportunistically, found in the Afroalpine. Among them, two subgroups are apparent: Group 4a comprises taxa with largely Afromontane distributions. Group 4b with more widespread forms inhabiting several other biomes as well.

Obligate Biome-Confined Breeding Residents (Group 1)

Ruddy Shelduck (**Fig. 4**), Golden Eagle and Red-billed Chough are the only bird species that show a distinct confinement to the alpine biome in Africa. They are resident only in the Ethiopian highlands. In spite of that, none of these species is restricted to Africa. In fact, their occurrences in the Afroalpine represent distinct southern breeding populations of their much larger Palearctic ranges where, moreover, they are also found outside of alpine zones. Their habitat requirements are thus varied and regionally incongruent across their whole breeding range (see also [Moreau, 1966](#)). In Africa, they co-occur because of locally overlapping habitats in the relatively small-scaled Afroalpine zone, apparently without much interspecific interaction.

Regular Biome-Affiliated Residents (Group 2)

Thekla Lark (ssp. *huei*), Brown Warbler (ssp. *griseiventris*), and the Ankober Serin are possibly the only true African birds with a strong affiliation to the Afroalpine, although their habitat requirements and lifestyles are not identical. While the Brown Parisoma is quite variable in terms of food (insects, seeds) and foraging methods and strata (on ground and in/on vegetation), the Thekla Lark is bound to a more terrestrial lifestyle while sharing a similar diet. In contrast, the Ankober Serin is confined to a strict diet of grass seeds which is obtained in much rockier habitats than the other birds. Again, these three birds are solely resident in the Ethiopian highlands.

Facultative Biome-Affiliated Residents (Group 3)

This group, consisting only of Afrotropical bird taxa, is represented both in the Ethiopian highlands and the East African mountains. They harbor the same small number of three species each, but form very different bird communities. Taxonomically, only two francolin species (Moorland and Elgon Francolin) represent the same bird family in the two geographic areas, respectively, whereas the

Fig. 4 The Ruddy Shelduck is among the few bird species with a distinct confinement to the Afroalpine in Ethiopia, where it represents an isolated southern breeding population of a much larger Palearctic range. Photo: T. Pröhl.

other species either belong to waterfowl (Blue-winged Goose, **Fig. 5**) and waders (Spot-breasted Plover, **Fig. 6**) or to songbirds (Red-tufted Sunbird and Moorland Chat). Biogeographically, the Ethiopian Afroalpine community consists exclusively of species that are only to be found there, whereas the East African community shares one species with group 4 of the Ethiopian highlands (Moorland Chat). In terms of lifestyle, the species differ in their habitat preferences: the francolins are found in areas of denser vegetation that provides shelter, the goose and plovers have a certain affinity to (temporal) water bodies, and the songbirds exploit the invertebrate fauna or the nectar of different flowering plants.

Opportunistic Residents and Visitors (Group 4)

This group contains only such species that are to be expected to occur repeatedly in the Afroalpine, based on current knowledge. The group comprises the largest overall number of 36 species, and some of them occur in the Palearctic and Indomalayan region as well. They are likewise found both in the Ethiopian highlands and the East African mountains. Again, there are differences, not only in Ethiopia having the larger species number (31 vs. 15), but also in the composition of the respective bird communities. For example, there are no francolins in the alpine East African mountain regions while two duck species (Yellow-billed and African Black Duck) appear to replace each other geographically. There are ten species that are encountered in both geographic locations while 20 species are solely found in the Ethiopian highlands and 5 solely in the East African mountains. By far the largest part of this group's species have a mainly Afromontane distribution (group 4a with 27 species) whereas 13 species are more widespread (group 4b). Moreover, the Augur Buzzard is assigned to group 4a in the Ethiopian highlands but to group 4b in the East African mountains, while the Moorland Chat of group 4a in the Ethiopian highlands is found in group 3 of the East African mountain bird community. Noteworthy taxonomically is the occurrence of four seedeater species alone in group 4a, while subgroup 4b is of particular interest because it contains numerous raptor species (among them typical migratory visitors like the Pallid Harrier). As a consequence of the diversity of avian taxa involved, this group cannot be defined on grounds of specific shared habitat requirements.

Noteworthy Distributional Peculiarities

Of the 25 non-passerine taxa assigned to the Afroalpine, 17 are raptors (including owls). Of the 22 passerine taxa, five are seedeater species belonging to two genera (*Serinus* and *Crithagra*). Some of these birds are worth a closer look as they play important roles in the avifauna of the Afroalpine, even though they might not be found there exclusively.

Fig. 5 The Blue-winged Goose is a regular inhabitant of the Ethiopian alpine zones. It is suspected to leave these areas seasonally, possibly following the availability of food or water. Photo: T. Pröhl.

Fig. 6 The Spot-breasted Plover apparently follows a similar occurrence pattern like the Blue-winged Goose in Ethiopia's alpine region. Photo: T. Pröhl.

Birds of prey fulfill important ecological functions either as top predators or carrion feeders. The relatively large raptor community encountered in the Afroalpine reflects both their high trophic levels in the food chain and the exceptional conditions of the biome: the necessity to remove carrion from alpine habitats and plentiful food sources (particularly small mammals, but also other birds) explains the speciose composition of the Afroalpine raptor community and their exclusive utilization of food resources (Clouet et al., 1999; Rödel et al., 2002).

Among them, the Bearded Vulture (Fig. 7) is commonly associated with barren high-mountain habitats, but this is just one component of their lifestyle. Bearded Vultures are apex elements of food chains, consuming even the last skeletal remains of vertebrate carcasses. Traveling over broad geographic distances, Bearded Vultures are extremely flexible in terms of hunting and breeding habits, and they are not confined to alpine regions. Although they are very widely distributed over many mountainous habitats across Africa, Europe and Asia, they occupy a wide range of lowland areas if occasion requires. Thus, the Bearded Vulture is a prime example of a nomadic species that opportunistically uses resources in the Afroalpine without being bound to this biome exclusively.

Fig. 7 The Bearded Vulture is a prime example for a nomadic species that opportunistically uses resources in the Afroalpine without being bound to this biome exclusively. Photo: T. Pröhl.

The Augur Buzzard (**Fig. 8**) represents a comparable situation to the Moorland Chat in being assigned to two different groups, although in this case only the sub-grouping of group 4 is affected. This means that the Augur Buzzard is a much more range-restricted species in the Ethiopian highlands (group 4a), where it is a regular visitor, than it is in the East African mountains (group 4b) where it occurs over a substantially larger area beyond the montane and alpine zones of the mountain ranges. It has been suggested by [Moreau \(1966\)](#) that the Augur Buzzard is only a visitor to the Afroalpine because of its dependence on the mountain forests for nesting sites, which might also explain its different distribution patterns.

Among the songbirds of the Afroalpine, the corvids (**Fig. 9**) represent a particularly interesting group in regard to their ecology. Being generally opportunistic birds with a great deal of adaptability to different environmental conditions, it is not surprising to find four corvid species in the Afroalpine. Among them, the aforementioned Red-billed Chough comes closest to being a genuine alpine bird (group 1), whereas the other three species are opportunistic residents and visitors to the biome only (group 4). It is obvious that the latter three are separated from the chough by very different and less habitat-bound lifestyles, including a much closer affinity to

Fig. 8 The Augur Buzzard is only a visitor to the Afroalpine because it depends on the mountain forests for nesting sites. Photo: T. Pröhl.

Fig. 9 Like some other corvids, the Thick-billed Raven has a certain affinity to human settlements. Therefore, potential future distributional changes in connection with the spread of settlements should be monitored carefully. Photo: T. Pröhl.

human settlements. Therefore, an open eye should be kept on the dynamics of potential future distributional changes of these corvids in connection with the spread of settlements.

The small Moorland Chat (**Fig. 10**) has previously been mentioned as a typical element of the Afroalpine (Moreau, 1944; Moreau, 1966; Salt, 1954 in Franz, 1979). Its regular occurrence in the Afroalpine is remarkable since insectivorous bird species usually are underrepresented in alpine habitats, possibly because of the scarcity of appropriate food. In fact, the Moorland Chat shows different distributional patterns in different parts of Africa: while it is a resident with some degree of affiliation to alpine habitats in the east African mountains (Kilimanjaro: Moreau, 1944; Salt, 1954 in Franz, 1979; Mt. Kenya: Coe, 1967), it is probably much more of a common visitor to the Afroalpine of the Ethiopian highlands than a regular inhabitant (personal observations). In terms of its taxonomy, the Moorland Chat consists of numerous subspecies across Africa but their respective association with the Afroalpine biome has not been studied so far. In contrast, the Brown Warbler and the Thekla Lark are represented by particular

Fig. 10 The regular occurrence of the Moorland Chat in the Afroalpine is remarkable since in many alpine habitats insectivorous bird species usually are underrepresented. Beyond that, it is one of the biologically most fascinating, but poorly studied birds of the African mountains. Photo: T. Pröhl.

subspecies that have a known close affiliation with the biome. Such geographical and seasonal differences must be taken into account when generalizing about the Afroalpine avifauna, especially since quantitative data on the relative proportions of Afroalpine and Afromontane breeding populations are lacking.

The seedeater taxa (**Fig. 11**) have a special position among African finches because they are comparatively species-rich and tend to occupy only small ranges, leading to a high degree of intra-generic endemism. In the Afroalpine, there are five seedeater species. As in the corvids, there is one species (the Ankober Serin of group 2) that is more closely affiliated with the biome, in contrast to the remaining four which are opportunistic residents of the Afroalpine (group 4). Apparently resource competition prevented these birds from co-habiting the biome with other species: the Ankober Serin has an extremely specialized diet of very small grass seeds, a food source that is not available throughout the Afroalpine in sufficient quantities to sustain larger populations of different species.

Moreover, swifts (Apodidae) and swallows and martins (Hirundinidae, **Fig. 12**) that are frequently encountered foraging on the wing usually remain unassigned to the biome, particularly if evidence of breeding is not produced (but see [Coe \(1967\)](#) who

Fig. 11 The Black-headed Siskin is one of five seedeater taxa in the Afroalpine. Photo: T. Pröhl.

claimed to have found disused nests of Alpine Swifts *Tachymarptis melba* on Mt. Kenya). Their widespread geographic distribution and lack of specific association with the biome, however, do not render them characteristic elements of the Afroalpine. Nonetheless, although species identification poses another challenge, we expect more species to be found in the Afroalpine than are listed in **Table 1** if more attention was focused on these neglected groups. Similarly, cisticolas (Cisticolidae) are underrepresented in observation records of Afroalpine avifaunas, most likely because of their difficult identification. Some cisticolas are found in high-elevation moorland areas (cf. [Moreau, 1966](#)), and although there might not be many, they deserve the effort of careful identification.

Community Transition Patterns

Typically, the overlap between two adjacent habitats (ecotones) forms a particularly species-rich community ([Lomolino et al., 2010](#)). In contrast, the transition zone between the Afromontane and the Afroalpine is not characterized by an enhanced number of bird taxa. This finding has an interesting parallel in terrestrial invertebrate groups (e.g., Carabid beetles) which also do not constitute a separate community above the Ericaceous belt on Mt. Kilimanjaro but an impoverished set of montane communities ([Franz, 1979](#)). However, this similarity should not be overly generalized since beetles on Mt. Kenya and in the Ethiopian highlands do appear to form specific alpine communities ([Franz, 1979](#)). Moreover, soil invertebrates and even small mammals are much less mobile and often more specifically bound to local ecological conditions than birds. The huge species diversity of shrews on isolated African mountaintops is an example of such regional diversification as a result of adaptive radiations (e.g., [Stanley et al., 2015](#); [Lavrenchenko et al., 2016](#)). In contrast, the mobility of birds combined with their ability to quickly avoid unfavorable conditions, may have prevented them from forming distinct Afroalpine communities.

Additionally, the temporal patterns of presence and absence of Afroalpine birds are not well understood and the potential effect and extent of elevational migration in the Afroalpine has scarcely been studied. In particular, members of groups 2 and 3 may perform temporal elevational migrations, thus shifting their ranges between the Afroalpine and the Afromontane, either regularly or opportunistically. Such movements have been found in Afromontane birds ([Brown et al., 1982](#)) and are likely to take place in some Afroalpine taxa as well. For instance, there is evidence that at least some species of the Ethiopian alpine zones (e.g., Blue-winged Goose or Spot-breasted Plover) apparently leave these habitats, possibly following the availability of food or water (personal observation), while their whereabouts outside their well-documented highland occurrences are virtually unknown. Moreover, at least for the White-collared Pigeon a daily movement between high-elevation foraging sites and much lower roosting sites has been described ([Boswall and Demment, 1970](#)) but such patterns of movement are insufficiently known for other Afroalpine birds.

Another aspect of particular ecological interest is the close dependency of raptors on small mammal communities in the Ethiopian Bale Mountains. The exceptional species richness and abundance of small mammals in this area sustains a likewise unusually speciose raptor community that opportunistically exploits this food resource ([Colwell et al., 2008](#)). This might explain why there are so many raptors found among group 4.

The numerical difference between the Ethiopian and East African Afroalpine bird taxa differs from the finding of [Moreau \(1966\)](#), who already suspected his assessment to be biased because of the then less well-known Ethiopian avifauna. Although the situation has since changed, the biological information thus far collected remains comparatively poor and requires further focused study.

Comparison With Avifaunas of Other Alpine Biomes

In contrast to the arctic tundra and alpine tundra-like biomes on high-elevation mountains of the Palearctic, where broadly disjunct populations of the same bird species occur in climatically and structurally similar habitats as a result of a Post-Pleistocene separation of ranges (e.g., the Rock Ptarmigan *Lagopus mutus* with regular occurrences in the European Alps and in the Northern tundra proper), there is no such situation of separated lowland and highland distributions of birds to be found in Sub-Saharan Africa.

The Afroalpine shows both similarities and differences in comparison to other high mountain ranges on other continents (noteworthy are the European Alps, the American Cordillera, the Himalayas of Asia and the Southern Alps of New Zealand). Direct comparisons of alpine bird communities exist between African and South American mountains but usually do not focus on alpine zones alone (e.g., [Löffler, 1977](#); [Dorst and Vuilleumier, 1986](#); [Hanz et al., 2018](#)). Nonetheless, basic patterns of morphological, behavioral and functional aspects are remarkably similar, despite phylogenetic differences. Obviously, similar ecological conditions apparently influenced the combination of traits of both Old World and New World bird communities in a similar way, so that ecological counterparts can be identified among many avian feeding guilds between the mountain systems of the two continents ("intercontinental convergence," [Dorst and Vuilleumier, 1986](#)). This is particularly pronounced in passerines, namely in small insectivores and nectarivores as well as in small seed-eaters ([Dorst and Vuilleumier, 1986](#)). Moreover, the availability of food resources and the structure of the vegetation appear to be more important drivers for the diversification of avian communities than abiotic factors like temperature and precipitation ([Hanz et al., 2018](#)). However, since abiotic factors have a strong influence on the structure and composition of the Afroalpine landscape, its impoverished avifauna may reflect merely its ecological opportunism and resistance towards unfavorable conditions rather than representing a truly specialized alpine community ([Moreau, 1966](#)).

Conservation Aspects

In conservation practice, the Afroalpine usually plays a subordinate role, being either included in a broadly defined “Afrotropical Highlands” biome (Fishpool and Evans, 2001) or forming a sub-biome “Alpine moorland” of “Montane grasslands and shrublands” (Burgess et al., 2004). While these assignments are generally useful with respect to the protection of large-scaled geographic units, the Afroalpine as a mosaic of species range fringes needs particular attention as a sensitive indicator of upcoming ecological changes.

Considering the potential effects of ongoing climate change and particularly of global warming on the African continent (e.g., Hulme et al., 2005), biological responses could be substantial in mountain systems as uphill elevational shifts of communities, either in part or as a whole, are to be expected (BirdLife International and National Audubon Society, 2015; Freeman et al., 2018a). As a consequence, species composition and associated functional features of communities along elevational gradients might change drastically (Colwell et al., 2008; Corlett, 2011). Potential scenarios could be extreme, including the extinction of species at the highest elevations (“mountaintop extinction”; Colwell et al., 2008; Chala et al., 2016; Freeman et al., 2018b), thus possibly affecting Afroalpine birds directly. Moreover, upward movements of animal communities might become restricted by a much slower shift of treeline, decoupling biological interactions and destabilizing communities (Dehling et al., 2014). Regarding the bird communities found in the Afroalpine regions, effects are difficult to forecast as most of them do not affect this biome alone. Climate-induced changes to plant communities might at least indirectly influence the species-rich Afromontane bird communities (Vollstädt et al., 2017), and may subsequently affect Afroalpine birds as well.

Unfortunately, climate change is not the only threat to the Afroalpine biome. A growing human population and acute land use changes such as massive deforestation, heavy agricultural intensification and livestock overstocking already directly impact even the fragile upper habitats of African mountains (Messerli and Hurni, 1990; Burgess et al., 2004; BirdLife International, 2018). It is thus important to be able to identify and anticipate threats to the Afroalpine and its bird populations since geographically large-scaled protection assessments usually do not differentiate between effects in the Afromontane and in the Afroalpine.

Perspectives

Many of the birds taxa associated with the Afroalpine have not been adequately studied with respect to their actual affiliation with the biome. Systematic monitoring data do not exist and basic biological information is often fragmentary. Some birds appear to be just regular visitors while breeding is incompletely documented. Biological data on food and resource utilization in general is available only cursorily. Relevant comparisons between Afroalpine and Afromontane populations of the same species have so far not been made. Also, further research is required to understand the temporal mechanism and the potential triggers of (regular?) elevational movements of the birds inhabiting the Afroalpine. All this is of particular importance considering the intensified land use in African mountain systems against the backdrop of ongoing climate change. A prioritization of practical conservation measures is necessary to guarantee their effectiveness but can only be based on well-founded research. Thus, we suggest systematic bird monitoring activities that are accompanied by structured studies focusing on key aspects of the biology (feeding, breeding, seasonality) of Afroalpine birds.

Conclusions

The number of avian taxa recorded in the Afroalpine is relatively small, particularly considering the speciose subjacent elevational zone, the Afromontane. However, there is no specific Afroalpine bird community, although a few taxa are more regularly encountered there than others, including a small number of endemics. By and large, the avifauna of the Afroalpine merely represents a greatly impoverished Afromontane community rather than a distinct community of its own.

As a consequence, the transition zone between the Afromontane and the Afroalpine is not characterized by an enhanced number of bird taxa. This is in contrast to the typical effect found at many habitat edges (ecotones), where members of two adjacent zones form a particularly species-rich community.

Further research is needed to comprehend the patterns of occurrence of Afroalpine birds and the biotic and abiotic triggers shaping their temporal and spatial distribution. A wary eye has to be kept on the effects of climate change as habitats on high elevations might suffer severely under persistent global warming.

Abstract

Alpine environments in South America occur essentially in the Andes, which extend along a latitudinal gradient between 11°N in Colombia and 55°S in Chile. The alpine biodiversity of the Andes is the richest in the world and it displays remarkable patterns of endemism, species radiations and morphological/physiological adaptations. In this article we aim at discussing the major biogeographical drivers of alpine biodiversity in the Andes and their consequent spatial patterns (i) in the past, (ii) at present, and (iii) in a near future under the influence of global change. Moreover, we briefly discuss the biogeography of smaller alpine environments in South America, that is, the Guayana highlands, Campos de Altitude and Tristan da Cunha Island. First, the evolution of the South American continent during the Mesozoic and Cenozoic greatly shaped biodiversity patterns in the Andes through mountain uplift and successive periods of geographic connectivity and isolation. Mountain building led to new niches that became available for colonization by both temperate and tropical species, while important topographic changes and the continental connection with North America provided either biotic corridors or sky islands. Second, Pleistocene glacial dynamics accelerated taxonomic diversification but also exacerbated extinction processes that substantially changed Andean biodiversity. Third, human activities have progressively influenced the structure and function of alpine ecosystems, leading to today's Andean biogeography. Current drivers of biodiversity distribution can be described at three spatial scales. At the continental scale, latitudinal shifts create strong variations in temperature seasonality, influencing, for example, snow cover duration and generating distinctive adaptations from the North to the South. At the regional scale, rain shadow effects, the Humboldt Current and trade winds combine with topographical and bedrock variations to create hotspots of endemism such as are found in the Sierra Nevada de Santa Marta (Colombia) or alpine deserts with specific life forms such as are found in the Central Andes. At the local scale, the spatial distribution of species is extended through habitat amelioration by nurse/engineering plants. These unique alpine ecosystems are highly vulnerable to the combined effects of climate and land use changes. High-Andean biota will undoubtedly respond to these changes by either adaptation, local/regional migration, or extinction. Extinction is already occurring at alarming rates in many taxonomic groups. Finally, we predict that new threats, such as biotic invasions and the creation of non-analog communities will directly affect biodiversity responses.

Introduction

By crossing the continent from one end to the other, the Andes are not only the largest mountain range in South America but also the longest continental mountain range in the world, spanning seven countries between latitudes 11°N in the Sierra Nevada de Santa Marta and 55°S in the Cordillera de Darwin. The Andes encompass large highland areas within and outside the tropics. In this article, we will refer to highlands as alpine environments *sensu lato*, whose ecosystems are constrained by low minimum temperature and are mostly located above the natural treeline (Körner, 2003). Alpine areas in the tropical Andes lie roughly between 3000 and 5000 m a.s.l. but they develop at sea level in boreal Patagonia, including outside the Andes. By hosting 38% of the immense Neotropical plant diversity (Antonelli and Sanmartín, 2011), the Andes are major contributors to South American

biodiversity. Spatial patterns of biodiversity include exceptional rates of endemism, very rapid species radiation rates (Madriñán et al., 2013) and the development of specific functional traits and life forms representing specific adaptations (Rundel et al., 1994). An outstanding example is the Páramo in the northern Andes, which is considered the most phytodiverse tropical-alpine province on Earth, with about 5000 plant species, 60% of which are endemic (Sklénář et al., 2014; Peyre et al., n.d.; Fig. 1).

To provide an overview of the biogeography of alpine Andean region and make exploratory scenarios for the future of the biodiversity, we divided this article into three sections: past, present and future. In each section we focus on the evolution of broad-scale spatial patterns of biodiversity and their biotic-abiotic drivers, and illustrate with diverse specific examples. We close the article by exploring the biogeographical features of the other, much smaller alpine environments of South America. Because of our experience as plant ecologist and phytogeographer, this contribution is centred on the biogeography of plants, without disregarding animals.

The Past

The geological and human histories of the Andes are greatly responsible for the substantial species diversification that happened through time on the South American continent, particularly their alpine environments. Among the most important factors that gave rise to Andean biodiversity and whose effects are sometimes difficult to disentangle are the mountain uplift itself, the presence of biogeographic barriers and migration routes, and extreme climatic fluctuations, followed by a posteriori anthropogenic remodeling (Fig. 2).

Andean Uplift and Altitudinal Migrations

The Andean uplift progressively allowed the creation, shaping and maintenance of a true Andean alpine belt with specific tropical alpine ecosystems. Regional subduction tectonics of the Pacific plates under the South American plate initiated in the Mesozoic (Jurassic-Cretaceous) and led to the initial uplift of the Central and Southern Andes, while draining the Amazonian sea that was covering most of central South America. The main orogeny of the northern, central and southern Andes took place during the Paleogene, especially Eocene and Oligocene (60–30 Myr). The northern Andes were geographically separated from the central Andes at the time by the Western Andean Portal (WAP), a relic of the Amazonian sea at $\sim 5^\circ\text{S}$ (Hooim et al., 2010). In the early Miocene (~ 23 Myr), the Pacific plates split, leading to a collision of the South American and Caribbean plates and resulting in an intensified uplift of the northern Andes. The mountain building of approximately 50% of the Andes consequently narrowed the Orinoco distal basin and allowed for a large watershed, the Pebas system, to occupy most of Amazonia (Hooim et al., 2010).

Fig. 1 Predicted local plant species richness across the Páramo biogeographical province, shown at a 30 arc-second (~ 1 km) resolution. The local richness predictions at plot scale were obtained using a Universal Kriging model, adjusting an environmental Generalized Least Squares model and spatial interpolations in form of an Ordinary Kriging model.

Fig. 2 Main events in high-Andean plant past biogeography: the Andean uplift allowing upheaval of species with adaptive capacity to the alpine environments; the Andean Highway migration route, which allowed north-south migrations along the cordilleras; the Great American Biotic Interchange (GABI) resulting in north-American taxa reaching and colonizing the Andes; the Glaciation dynamics that promoted diversification through rapid lower-upper movements of the treeline and snowline.

However, the most intense orogeny phase for the region came later, during the Mid-Miocene (~10 Myr) and early Pliocene (~4.5 Myr), with the Andes reaching 60% of their present elevation in this short period (Garziona et al., 2008). Finally, by the end of the Pliocene, the western Colombian cordillera emerged, completing the last significant uplift of the Andes.

With the Andean uplift, new topographic and environmental heterogeneity was created, leading Andean and outer-Andean species to adapt in different ways. In fact, the Andes form a strong barrier separating the lowland species from either the Pacific or Amazonian-Pampa sides. At the same time, the raising cordilleras created new niches and provided biotic temperate corridors, which allowed for mountainous species to disperse and radiate (Antonelli and Sanmartín, 2011), especially in the mostly continuous tropical Andes and to a lesser degree in the more isolated southern Andes. Finally, the highly diverse species pools of the lowlands, for example, from the Amazonian and Chocó biomes, contained many taxa with adaptive capacities that escaped these overly saturated lowland areas and dispersed to colonize alpine areas (Antonelli and Sanmartín, 2011). This pattern was observed for many taxa such as tropical bamboos and bromeliads (Sklenář et al., 2011; Fig. 2).

Geographic Isolation and Latitudinal Migration Routes

The WAP in northern Peru constituted one of the most important biogeographic barriers to alpine biodiversity during the Andean orogeny, because its low elevation at sea level and marine influence greatly limited species' dispersal. The WAP gradually closed ~12 Myr, allowing species to cross over from the south-central Andes to the northern Andes and back, hence creating the "Andean highway migration route" (Antonelli and Sanmartín, 2011). For example, *Azorella* is an Austral-Antarctic plant genus that used this path to colonize the newly available northern Andes from the south (Nicolas and Plunkett, 2012; Fig. 2). By the end of the Miocene, the Pebas system had drained and the Marañón River dug the narrow Huancabamba depression through the Andean cordillera in northern Peru, thereby creating a new biogeographical barrier to the dispersal of high elevation taxa, as observed for birds (Hazzi et al., 2018).

South America became an isolated continent during the Cretaceous and therefore independently developed a very ancient and largely endemic biota (Smith and Klicka, 2010). This isolation continued until the uplift of the Panama isthmus, which connected the continent to North America ~3 Myr ago, resulting in the Great American Biotic Interchange (GABI; Antonelli and Sanmartín, 2011). However, many high-elevation animals and plants may have crossed between the two continents before the final closing of the Panama Isthmus, probably through long distance-dispersal and island hopping, for example, the genus *Valeriana* in the Miocene (Bell and Donoghue, 2005). Biotic migrations greatly accelerated with the GABI (Hoon et al., 2010). For example, the Holarctic temperate genera *Lupinus* (Hughes and Eastwood, 2006) crossed the isthmus to colonize the northern Andes and radiate south, eventually reaching Patagonia. Other plant taxa with representation in the Neotropical lowlands and highlands such as *Pitcairnia* and *Tillandsia* successfully migrated and colonized Central America using the GABI (Givnish et al., 2014). An equal exchange of taxa occurred between the two continents, as observed for mammals, birds and plants, however, taxa moving to South America usually proved more successful than those that migrated in the opposite direction, resulting in important species accumulation in the South American lowlands and but also in alpine areas (Smith and Klicka, 2010). For example, for mammals, 50% of modern South American genera have North American origins, whereas only 10% the other way around (Marshall et al., 1982). Therefore, the Andean alpine belt became considerably species-enriched, especially regarding plants but also animals, thanks to these new latitudinal migration routes trespassing previous geographic barriers.

Glaciations and Taxonomic Diversification

By the end of the Pliocene, most of the Andes had reached their modern elevation and presented mountain forests topped by grass- and shrub-dominated alpine communities, precursors of the Puna and Páramo biogeographical provinces (Garziona et al., 2008). During the Pleistocene, species diversification amplified in the high Andes, mostly driven by glacial dynamics. In comparison with other continents, South America was generally less affected by ice cover and temperatures were generally only 5–10°C lower than today (Sandel et al., 2011). The Neotropics, especially the lowlands, acted as a biological refuge, enhancing species accumulation through niche conservatism and speciation time mechanisms. The Andes experienced ~20 glacial-interglacial cycles in the Pleistocene, consisting roughly of 90% glacial epochs and 10% interglacial epochs. These climatic cycles influenced and sped the differentiation of both alpine flora and fauna. For example, glaciations shaped the Páramo as the coolest and fastest evolving hotspot in the world (Madriñán et al., 2013).

During glacial epochs, the elevation belts shifted downslope greatly, down to 1000–1500 m for the northern Andes and increased considerably their surface area, for example, the Páramo increased by three times its modern size (Flantua and Hooghiemstra, 2018). Alpine species usually migrated downward and radiated through the continuous elevation belts, whereas extra-Andean species concentrated in lowland refugia. In contrast, during interglacial epochs, elevation belts gradually rose up and isolated the Páramo and the Puna, creating mountain biogeographic islands (Flantua and Hooghiemstra, 2018). At this time, the organisms that could keep up with climate change became isolated and speciated, contributing to the important endemism that is observed today (Hughes and Eastwood, 2006). In parallel, the contingent lowlands lost species that used this opportunity to further colonize mountain areas, as observed in birds (Hazzi et al., 2018). A good example of Pleistocene-induced diversification is the Asteraceae subtribe Espeletiinae, which appeared at the end of the Pliocene in Venezuela and radiated along the Colombian cordilleras, reaching Ecuador during the Pleistocene, speciating into about 60 species in the process (Fig. 2).

Human Influence

The first evidence of human presence in the Andes goes back to 15,000 year BP (Wheeler, 1984) with testimony of hunter-gatherer human behavior in the humid Puna of Central Peru. Occupation records for the dry Puna of the south-central Andes go back to around 10,000 year, and it is not until 6000 year that traces of domestication were encountered and showed the first signs of settling and grazing-agricultural activities (Wheeler, 1984). Such domestication occurred principally in the Central Andes and included animals, that is, llama and alpaca, and plants, that is, potato and quíñua. The expanding and increasing activities slowly caused environmental impacts; nonetheless, it is only in the case of broad-scale human migrations such as the Inca's through Bolivia, Peru and Ecuador that said impacts influenced the general alpine landscape and biogeography. For example, *Polylepis* forests were believed to dominate the treeline around 4000 m for most of the Pleistocene and the authors hypothesize that humans gradually deforested the treeline (Fjeldsø, 1992). In comparison with the central and later southern Andes, the northern Andes remained mostly unoccupied until Spanish colonization, with only scant evidence of nomad hunter-gatherer practices after AD 1200 and no important development of permanent settlements (Molinillo and Monasterio, 2002).

The Spanish colonization of the Andean countries in the 16th century brought many important environmental impacts on the alpine ecosystems and their species, especially in the relatively pristine northern Andes. The strictly controlled grazing and agricultural practices of pre-Colombian societies were quickly replaced by more extensive methods combined with the introduction of new crop and cattle species, for example, cow, sheep, and goat (Molinillo and Monasterio, 2002). The lower alpine elevations were usually used for crops, whereas higher elevations were used for unregulated grazing. Moreover, it was common to associate grazing areas with frequent burning of the existing biomass to create more palatable grasses for cattle, hence homogenizing large landscape areas (Hofstede et al., 2003). In parallel, settling land-owners progressively promoted new adapting grasses to increase the foraging quality, originally either local species from local lower elevations such as *Paspalum* and *Bromus*, or alien species, like *Pennisetum*, *Holcus*, and *Anthoxanthum* (Molinillo and Monasterio, 2002). The anthropogenic pressure kept increasing with time, with humans diversifying and accelerating their activities with the successive technological advances and agrarian reforms, especially in the second half of the 20th century (Hofstede et al., 2003). Each innovation of human practices intensified and expanded geographically, slowly replacing native, specialized species, selecting opportunistic species and allowing for aliens to intrude the alpine belt, while the landscapes became homogenized over broad-areas and fragmented in others. Therefore, the anthropogenic history of the Andean highlands has played a significant role in progressively shaping the spatial patterns of biodiversity found today, forming the basis of their future evolution.

The Present

Effects of Latitude (Continental Scale)

Several Andean biogeographical provinces have been described along the Andean latitudinal gradient, without focusing specifically on the alpine belt. We propose a simple and focused classification inspired from existing works (Fig. 3). The tropical Andes host two biogeographical provinces with strong dissimilarities in their environment and biodiversity (Cuesta et al., 2017): (i) the wet Páramo province with reduced seasonality in the northern Andes and (ii) the drier and more seasonal Puna located in the central Andes. Further south, the Mediterranean high Andes occur from 25°S (Antofagasta) to 39°S (Osorno) and are defined by a pronounced dry season and precipitation concentrated during the austral winter. This biogeographical province encompasses the Prepuna as defined by Morrone (2006) and includes an enlarged area of the Mediterranean Andean region as described by Rivas-Martínez et al. (2011). The southernmost province is Patagonia, which can itself be divided into temperate and boreal provinces. More pronounced seasonality to the South increasingly influences Patagonian biodiversity, with higher variations in photoperiod and reduced growing season for plants. Accordingly, although alpine vegetation is characterized by a high level of environmental homogeneity worldwide, especially due to low minimum temperatures (Körner, 2003), the extended latitudinal gradient shaping the Andes gives opportunities for living organisms to develop specific adaptations. We describe below some of the prominent effects of the Andean latitudinal gradient on the alpine biodiversity distribution in the Andes.

Temperature seasonality increases markedly with latitude, affecting patterns of alpine biodiversity. The latitudinal effect is almost nil close to the Equator while reaching maximum values in Patagonia, where it is responsible for long snow cover duration during winter. Conversely, at low latitude, daily temperature variations increase and generate diurnal freeze-thaw cycles because of the absence of protective snow cover at night (Rundel et al., 1994). The distribution of alpine biodiversity is strongly driven by the spatial and temporal distribution of snow cover, especially because of its ability to protect plants against cold temperatures at night. Accordingly, whereas most alpine plants share dwarf shapes and crucial investment in root structure, low-latitude climatic patterns promote specific adaptations to the absence of snowpack. This includes higher ratios between the plant's aerial and root biomasses with, for example, the development of giant alpine life forms (Rundel et al., 1994; Fig. 4). Other adaptations at low latitude include tolerance of temperatures that may drop as low as -20°C almost every night, through (i) the development of large, hemispheric cushions able to ameliorate microenvironments (e.g., *Azorella compacta* Phil.; Fig. 2) or (ii) the accumulation of soluble sugar in *Polylepis tarapacana* Phil. as a freezing avoidance mechanism, which also allows growth activity most of the year (supercooling; Rundel et al., 1994; Fig. 4).

Another latitudinal effect builds on a mismatch between the dry and the cold season outside versus inside the tropics, which represents the transition between the Puna and the Mediterranean high Andes (Fig. 3). Being sufficiently far from the equator, the

Fig. 3 Distribution of mountains and alpine biogeographical provinces in South America. Red arrows indicate steep climatic variations: *: seasonal mismatch between precipitation and temperature above and below the Tropic of Capricorn (23°S); other arrows are examples of rainshadow effects at different latitudes along the Andean Cordillera, in relation with the effects of trade winds and the Humboldt Current.

Puna is significantly influenced by annual temperature variations. Whereas precipitations concentrate between November and March during the “warm” season (*Bolivian winter*), it experiences a cold season, which usually peaks in July and August and coincides with the lowest precipitation amounts. These cold, dry conditions create a stressful period for organisms, with the combined effects of minimum temperature and drought in the absence of protective snow cover. Outside the tropics (Mediterranean), this pattern changes, with precipitation falling during the cold season, mostly as snow. Interestingly, the disjunct distribution of the cushion peatland species *Patosia clandestina* (Phil.) Buchenau with significantly distinct leaf traits in these two provinces suggests that the

Fig. 4 Alpine plant sizes in the Andes. Giant life form is a specific adaptation likely due to the absence of durable snow cover in tropical alpine regions. Weber ex Rümpler) (Puna; up to 9 m, pers. obs.). See also *Espeletia occidentalis* A.C.Sm. in Fig. 6. Dwarf life forms develop in all alpine environments of the Andes. (D) *Xenophyllum humile* (Kunth) V.A.Funk, 3600 m (Páramo). (E) *Lysipomia muscoides* Hook.f., 3200 m (Páramo).

contrasting seasonality, combined with an important physiological barrier (alpine desert) may lead to speciation processes (unpublished data; Fig. 5).

The elevation of alpine environments in the Andes decreases steadily with increasing latitude, from 3000 to 5000 m near the equator to sea level in southern Patagonia. At higher elevations, UV radiation increases and atmospheric oxygen decreases, posing additional constraints for living organisms through tissue damage and reduced respiration. Moreover, elevation increases atmospheric aridity, both through reduced relative air humidity and a significantly lower amount of precipitation above 2000–3000 m, known as the inverted rainfall gradient (Nagy and Grabherr, 2009). To withstand these particular constraints, tropical alpine plants have developed specific adaptations. They include overrepresentation in the Páramo and the Puna of (i) small, microphyllous, perennial leaves to limit desiccation, (ii) dense hairiness in leaves, stems and flowers to avoid damage from UV radiation, desiccation, the effects of cold temperature, and to increase stomatal activity (Rundel et al., 1994), and (iii) nodding capitula to ensure floral development and protect them from the negative effects of precipitation (Sklénář, 1999; Fig. 6).

Effects of Regional Parameters

High Andean summits have been shown to generate rain shadow effects that give birth to strong climatic variations and influence species distribution. Rain shadow effects can occur in the presence of several sequential mountains, as in Colombia and in Venezuela, in the presence of a high Andean plateau located between two cordilleras, for example in Bolivia, or between two sides of a single mountain, as in Ecuador (Mount Chimborazo; Sklénář and Lægaard, 2003). In each case, topographical barriers reduce precipitation from the West (humid Pacific influence) or from the East, (humid Atlantic influence and/or humid Amazonian influence brought by trade winds; Fig. 3). In temperate Patagonia, annual precipitation levels decrease from 3000 mm to 500 mm in only 80 km from the East to West (Veblen et al., 2003). Rain shadow effects are easily detectable in the high mountains bordering Amazonia, with glacier fronts located at lower elevations on their eastern side than on their western side. In the Páramo province, the climatic variability attributable to rain shadow effects has had a significant influence on patterns of plant richness and species distribution into phytogeographical units (Peyre et al., n.d.).

The vicinity of Amazonia on the eastern flank of the Bolivian Andes has created extrazonal páramos in the Puna biogeographical province, which share a significant number of taxa with the Páramo biogeographical province in the northern Andes (Páramo Yungueño). Interestingly, the major influence exerted by neighboring ocean on the climate of south-western Patagonia (hyper-oceanic bioclimate sensu Rivas-Martínez et al., 2011) seem to have created other extrazonal páramos at latitudes of approximately

Fig. 5 Disjunct, potential distribution of the cushion peatland species *Patosia clandestina* within and outside the Tropics (left) with individual of each population displaying distinct leaf traits thought to source from seasonal mismatch (right).

Fig. 6 Common morphological adaptations of plants to high elevation in the tropical alpine Andes, not frequent at higher latitudes. (Left) Microphyllous, coriaceous leaves in *Chuquiraga jussieui* J.F.Gmel. (Rucu Pichincha, Ecuador, 4400 m). Centre: hairiness in the leaves and flowers of *Espeletia occidentalis* A.C.Sm. (páramo de Belmira, Colombia, 3100 m); see also *Lasiocephalus ovatus* Schltdl. in Fig. 8. (Right) Nodding capitula in *Senecio serratifolius* (Meyen & Walp.) Cuatrec. (Cordillera Real, Bolivia, 4860 m). The palm species *Ceroxylon parvifrons* (Engel) H.Wendl. also adapted to the tropical alpine climate (centre).

50°S (Magellanic Páramo; Morrone, 2006; Fig. 3). Characterizing the connections between the northern Andean Páramo, the Páramo Yungueño and the Magellanic Páramo constitute an interesting scientific perspective to better understand the biogeographical processes shaping the alpine biodiversity of the Andes.

Under the influence of the cold Humboldt marine current from the coasts of central Chile to southern Ecuador, precipitation coming from the Pacific Ocean is sharply reduced (Fig. 3). This regional pattern gives birth to arid alpine environments on the western side of the Andes, adding to climatic heterogeneity and contributing to the existence of the Puna and the Mediterranean high Andes. The rain shadow effects, combined at some places with the effects of the Humboldt current, have created alpine deserts, where species have adapted and created specific forms and strategies, not only to cope with atmospheric aridity but also with edaphic drought. Grass species such as *Festuca orthophylla* Pilg. (Puna), trees such as *Polylepis tarapacana* Phil. (Puna) and even the caulescent rosettes (*Coespeletia timotensis* (Cuatrec.) Cuatrec., Venezuelan Páramo) are examples of species that have adapted and developed spotted patterns so as to avoid root competition among individuals of their own species in alpine deserts. In parallel, cactus species (Cactaceae), are observed in the Puna up to 4500 m (*Cumulopuntia boliviana* (Salm-Dyck) F. Ritter and *Lobivia pentlandii* (Hook.) Britton & Rose; Meneses et al., 2015; see also Fig. 4).

Beside the climate, geo-edaphic conditions and the topography are important drivers of biodiversity patterns in the alpine provinces of the Andes. Apart from metamorphic and sedimentary bedrocks, the high Andes are partly made of volcanic bedrock. For example, most of the Ecuadorian páramos are found on volcanic substrates, which has been suggested to favor the development of high microendemism in carabid beetles (Moret, 2009). The volcanic soils of the páramos have also been shown to develop exceptional properties of water retention, generating hydromorphic ecosystems within specific assemblages of plants (Poulenard et al., 2003). From a topographical standpoint, the north and the extreme south of the Andes are particularly fragmented (Fig. 3), giving birth to an archipelago of alpine areas where patterns of speciation have been documented for several organisms (review in Anthelme et al., 2014b). This fragmentation has given birth to particularly uncommon vegetation patterns such the occurrence of a cold-adapted palm in the Páramo, up to 3600 m (*Ceroxylon parvifrons* (Engel) H. Wendl.; Sanín et al., 2016; Fig. 6) and microendemism in aquatic invertebrates developing in glacial-fed streams (Jacobsen and Dangles, 2017). Small alpine areas separated by large distances from main alpine areas have created alpine environments with outstanding endemism in plants, birds and invertebrates, as in the Sierra Nevada de Santa Marta, Colombia (Anthelme et al., 2014b; Fig. 3). In the Ecuadorian volcanoes Reventador and Sumaco, strong isolation and volcanic activity has led to early successional Páramo plant assemblages likely brought by long-distance dispersal (Løjtman and Molau, 1983). Conversely, the rest of the Andes, from the north of Peru southward, display an alpine continuum represented by the Andean Altiplano. These regions have developed fewer endemic species assemblages.

Biogenic Amelioration of Habitats (Local Scale)

Alpine environments have been shown to host plant communities strongly driven by positive interactions between plants through biogenic amelioration. This takes place at the local level, but it well prove to be as important as predictor of future plant diversity as the effects of climate change in alpine environments, as proven with several studies conducted in the Andes and other alpine environments (*stress-gradient hypothesis*; Cavieres et al., 2014). At the ecosystem scale, some cushion species generate high Andean peatlands. These are extensively distributed in the Andes from Colombia to Chile and Argentina and provide habitats for a significant number of associated plants along a wide altitudinal range, such as *Gentiana sedifolia* Kunth, *Oritrophium peruvianum* (Lam.) Cuatrec. and *Werneria pygmaea* Gillies ex Hook. & Arn., (Fig. 7). The presence of large cushion-forming plants in the Páramo provide carabid beetles with local refuges that partly explain the high rate of endemism found in the high tropical Andes (Moret, 2009). These examples attest to a significant impact of nurse plants in reducing biogeographical barriers for other plants and animals.

Fig. 7 The Engineer/nurse species *Distichia muscoides* Nees & Meyen (centre) creates alpine peatlands that host similar species on an extended latitudinal gradient, for example, *Gentiana sedifolia* Kunth: in Bolivia on the left, in Colombia on the right.

The Future

Tropical Andean mountains are classified as *highly vulnerable* by the Intergovernmental Panel on Climate Change (IPCC), this mostly due to their geographic position, elevation, environmental heterogeneity and high biodiversity in terms of species and ecosystems.

Global Change

Predicting the effects of climate change on biodiversity is particularly difficult in tropical mountain areas. However, most authors agree that temperatures will increase up to 3°C (± 1.5) in the most vulnerable areas such as the Andean Páramo. Higher temperature anomalies, that is, increases of 0.1–0.3°C have been observed in the tropical Andes during the second half of the 20th century (Buytaert et al., 2011). Overall, Andean areas at relatively low elevation and close to the cooling humid lowland hotspots (Amazonia, Chocó) are less likely to suffer drastic temperature changes than high elevation areas in drier climates. Higher levels of precipitation are predicted for the coming decades in the northern Andes, up to +300 mm/year, apart from the Caribbean-facing mountains which may receive less precipitation (Buytaert et al., 2011). Increased seasonality is predicted for the Central Andes, with an overall extension of dry periods. In addition, temporal, spatial and intensity changes in the Pacific Decadal Oscillation, El Niño Southern Oscillation, and position of the Inter-Tropical Convergence Zone, will undoubtedly affect Andean meso- and microclimates, especially regarding precipitation patterns. Finally, the retreat of glaciers is a predominant issue, with glaciers thinning between 0.6 and 1.2 m/year in the tropical Andes, usually faster in the northern Andes in comparison with central Andes (Rabatel et al., 2013). Moreover, anthropogenic responses to climate change are predicted to have an even greater impact than climate change itself. Human population and activities will increase, intensifying impacts in already-occupied regions and bringing impacts to areas currently unavailable, for example the raising of the agricultural frontier above 4200 m in the northern Andes (Hofstede et al., 2003).

Biodiversity Response

Because of the diversity and complexity of the alpine environments of the Andes, it is particularly challenging to maintain species, ecosystems and their ecological equilibrium in the future. Facing global change, species can adapt, migrate or go extinct. It is expected that many Andean species will adapt their life cycle or physiology, for example so they can handle more extreme climatic events and fluctuations as shown for plants (Sierra-Almeida and Cavieres, 2010). In addition, distribution, and richness patterns could drastically change, for example, frogs and toads are shifting to higher elevations in the Peruvian Puna (Seimon et al., 2007). Such migrations can be impaired near the mountaintops where available niches and dispersal deficiency become limiting factors (Peyre et al., 2018; Fig. 8). Increase in local extinction rates of species or communities, as well as changes in phenological patterns are also expected to occur. Some authors predicted an extinction rate of almost 60% of plants by 2080 for the northern Andes, but smaller-scale studies revised this rate to 10% for high-elevation plants in the alpine Ecuador by 2100, although this number is still very problematic due to the fact that most threatened species are endemics (Peyre et al., 2018). At the ecosystem and biome level, drastic changes regarding species distribution and assemblages could also occur. For example, it is expected that the alpine plant communities of Ecuador will suffer drastic changes in terms of species assemblages and richness decreases, especially along the Amazonian flank (Peyre et al., 2018). Changes at the community level can however be buffered by the maintenance of microclimatic and edaphic conditions, for example, nurse plants and their associated biota (Anthelme et al., 2014a).

Invasive Species and Non-Analog Communities

Invasive species represent a serious issue in most of the alpine belt of the Andes, but especially in the northern range. The invasive strategies of such species and whether they move or extend their ecological niche in the Páramo and the Puna remain

Fig. 8 Picture (A) and distribution changes (B) of *Lasiocephalus ovatus* (Asteraceae) in the Ecuadorian super-páramo belt (4000–5000 m) under the effect of Climate Change for the period 2010–2100 (under the BCCCSM1-1 global climate model). Colors indicate where the species has remained (black), expanded (green), retracted (yellow) and where it could possibly be but could not disperse by 2100 (pink).

understudied. Five main drivers are usually associated with invasions in high mountains: (1) pre-adaptation to abiotic conditions, (2) disturbances, (3) biotic resistance of local communities through strong interactions, (4) propagule pressure, and (5) capacity to create synergic interactions with local species (Pauchard et al., 2009). Given the harsh environmental conditions, most invasive species in the Andes are plants, for example the shrub *Ulex europaeus* L. and herb *Rumex acetosella* L. in the northern Andes, or the tree *Pinus contorta* Douglas ex Loudon and the herb *Taraxacum officinale* (L.) Weber ex F.H.Wigg. in the southern Andes. However, animals, especially invertebrates, can only intrude and proliferate in the alpine belt, for example Pterophoridae (plume moths) are invading and weakening Espeletiineae species in the Páramo (Salinas et al., 2013). Disease incidence and impacts are also favored by climate change, as illustrated by the spread of frog pathogens through species migration and community re-assemblages in the central Andes (Seimon et al., 2007). Finally, new alpine niches will become available, especially related to glacier melting, and these areas are prone to important invasions and formation of non-analog communities comprised mostly of opportunistic and invasive species (Walther, 2004).

Other Alpine Environments of South America

Guayana highlands (GH): also called Pantepuis, the GH are table mountains mainly distributed in the tropics of Venezuela, with several extensions in Brazil, Colombia and Guyana. These highlands reach a maximum elevation of 3014 m at Sierra de la Neblina (Fig. 3). From a morphological viewpoint, the (sub)alpine plants observed in the GH are relatively similar to their tropical Andean counterparts, and form a “páramoid” vegetation (Huber, 1994). However, their pronounced geographic isolation has given birth to a high degree of endemism at the species level whereas endemism at the genus level is relatively low as a result of substantial connections between the GH and the lowlands, as evidenced with shared taxa. Some important taxonomic/functional groups are shared with the Andes (e.g., Asteraceae stem rosettes), whereas other important groups such as the Poaceae are comparatively less represented (Rull and Vegas-Vilarrúbia, 2006). The absence of a dry season in the GH and their limited elevation may explain certain differences with their Andean counterparts, such as the presence of broadleaved meadows. Up to one-third of the GH endemic plants are expected to be under threat of extinction by 2100, under temperature increase scenarios of 2–4°C (Rull and Vegas-Vilarrúbia, 2006).

Campos de altitude: the Campos are cool-humid, highly fragmented Brazilian alpine areas developed between 1800 and 2000 m and 2890 m in the Serra do Mar, the Serra do Caparaó and the Serra da Mantiqueira, between latitudes 20 and 23°S (DeForest Safford, 2007; Fig. 3). Ecological similarities have been described between the Páramo and the Campos, based on a significant percentage of shared species. The Campos are floristically closer to the tropical Andes and other Brazilian highlands than they are to the adjacent lowlands, suggesting that their species are adapted to an alpine climate. A significant part of the Campos flora is of temperate origin and might therefore have migrated through ancient favorable habitats instead of recent long-dispersal processes (DeForest Safford, 2007).

Tristan da Cunha Island: located at latitude 37°5S in the Atlantic ocean and influenced by a hyper-oceanic, temperate climate, Tristan da Cunha is part of a group of three Brazilian islands, considered as some of the most isolated in the world. Tristan da Cunha is a volcano that reaches a maximum elevation of 2060 m. The top of the island supports an alpine desert because of exposure to persistently high winds and recurrent soil instability due to solifluction and frost-heaving (Wace and Holdgate, 1958). These particular conditions partly explain the dominance of bryophytes and lichens and the absence of vascular plants at high elevations.

Still, we hypothesize that pronounced isolation combined with recurrent volcanic activity has led to the absence of nurse/engineer plants, such as the Austral-Antarctic genus *Azorella*, which could potentially facilitate ecological succession and improve the environment for other organisms. The island's dominant plant species demonstrate (1) that long-distance dispersal may have been partly effective from Patagonia (*Empetrum nigrum* L.) and (2) that the human presence since 1810 has generated strong invasion patterns (*Rumex acetosella* L.; Wace and Holdgate, 1958). Also, closely related species of snails in Tristan da Cunha and the Azores islands suggest that long-distance dispersal has partly shaped the island's biodiversity by connecting two temperate environments separated by the intertropical zone (Gittenberger et al., 2006).

Conclusion

A large body of literature on the past, current and future distributions of alpine biodiversity of South America has been made progressively available, evidencing a large panel of patterns and mechanisms for different taxonomic groups. This article was an attempt to confront these contributions, with the aim to provide relevant explanation on the biodiversity patterns observed today and predict their changes in the future. The unprecedented extensions of latitudinal and elevation gradients shaping the Andes are major drivers of biodiversity variation since the formation of the South American continent. Threats include the increasing impacts of human activities through changing climate and land use intensification. We expect them to have a major influence on the future of alpine biodiversity in South America, through accelerated migrations, substantial adaptations and induced vulnerabilities due to increasing habitat destruction, anthropogenic biogeographical barriers, and invasions by introduced taxa. The specific resistance and resilience abilities of species and ecosystems will be crucial parameters to understand the future distribution of a unique and endemic biodiversity.

Glossary

Adaptive radiation The rapid diversification of closely related species into distinct ecological niches.

Allopatric speciation The divergence of two geographically isolated species from a common ancestor.

Alpine biome A treeless habitat found at high elevation or high latitude, characterized by cold daily and annual temperatures, and tundra vegetation.

Biogeography The study of species distributions in space and time.

Cloud forest biome A subtropical or tropical evergreen montane forest with persistent cloud cover, characterized by relatively cool and wet conditions.

Ecological divergence The divergence of a lineage through time resulting in the occupation of a novel ecological niche.

Endemism The number of species found exclusively in a defined geographical area.

Evenness The total number of species (richness) weighted by the relative abundance of species found in a defined geographical area.

Föhn wind A warm, dry wind that first moves upslope to high elevations and then downslope on the leeward side of a mountain range, and is generated by a rain shadow (orographic) effect.

Highland Any mountainous region or elevated mountainous plateau.

Katabatic wind A cold, dry wind that moves downslope from higher elevations, and is generated by the force of gravity acting on high-density air.

Latitudinal diversity gradient A decline in global species richness from the equator to the poles.

Orogeny The geological process of crustal folding that causes mountain formation.

Orographic precipitation As warm, moist air moves up a mountain slope, it cools (adiabatic effect) and clouds form, eventually leading to precipitation on the windward side of the mountain. This leads to a rain shadow effect on the leeward side.

Parapatric speciation The divergence of two species in close geographical proximity (abutting geographical ranges) from a common ancestor.

Peripatric speciation Similar to allopatric isolation, in that there is divergence of two geographically isolated species from a common ancestor, but where one of the new species is formed as a small peripheral isolate of the more broadly distributed species.

Rain shadow A dry region on the leeward (downwind) side of a mountain, produced by the removal of moisture from air as it moves up and over the mountain slope.

Species richness The total number of species found in a defined geographical area.

Subalpine biome A transitional habitat, from closed woodland (timberline) to the upper elevation limit of trees (treeline), but encompassing forest, meadow, and bog habitats.

Sympatric speciation The divergence of two geographically co-occurring species from a common ancestor.

Windthrow A term in forestry used to describe trees that have been uprooted or broken by intense wind.

Abstract

North American highland habitats harbor exceptional species diversity, as well as high endemism in several distinct biomes. These include the cloud forest biome, subalpine biome and alpine biome found at high elevations in tropical and temperate mountains. Understanding the distribution of biodiversity in highland habitats, as well as the origin of endemic species, provides general insight into the evolutionary processes that generate new species. Major highland areas stretch from the Arctic Circle to the tropical southern border of Mexico, in a complex of old and young mountains. However, these highland areas are isolated from one another, and while highland species appear to be closely related across mountains, distinct endemic species are often found. Geological and paleoecological evidence suggests that past glacial climate fluctuations increased the connectivity of highland habitats, facilitating the movement of highland species during cool and wet climate episodes. Genetic studies of different plant and animal species have shown that the evolution of highland species has been rapid, with the distributional shifts from past climate change facilitating allopatric and peripatric speciation. Furthermore, in some rare cases, evolutionary divergence across steep ecological gradients found on mountain slopes has led to parapatric or sympatric speciation, with some lineages exhibiting adaptive radiation into novel ecological niches. Due to the wealth of biodiversity in these habitats, and the additional importance of highlands for the ecosystem services they provide to human communities, there is considerable concern about ongoing habitat destruction and climate change impacts on North American highlands.

Introduction to North American Mountain Regions

Highland habitats are of considerable interest in the study of biodiversity, as they not only contain high numbers of species, but reflect the outcomes of multiple processes that generate diversity (Steinbauer et al., 2016; Hoorn et al., 2013). This includes variation in environmental factors (climate, soils, elevation, etc.), geographical factors (riverine and montane barriers), and historical factors (geological and climatological change) that interact at a small spatial scale. Furthermore, these habitats are often insular in nature, functioning as “sky-islands” for the distinct montane biomes they contain relative to intervening low elevation habitats that act as natural barriers for highland species (Brown, 1971; Howell, 1947). Thus, highland habitats are often used by biologists as natural laboratories to disentangle the importance of different factors in generating and maintaining biodiversity (Badgley et al., 2017), as well as determining the factors that influence the distribution of species (the field of biogeography).

Beyond their importance to biodiversity studies, highland habitats provide a wealth of natural resources and ecosystem services (Egan and Price, 2017). These range from forest products, geological ores and game animals, to water storage, provision and filtration of water, carbon storage, and natural erosion of nutrient rich soils that enhance downstream agroecosystems. Additionally, they are often known for an array of natural features (waterfalls, soaring vistas, rock formations, pristine rivers, etc.), as well as indigenous cultures and ethnic diversity (Payne et al., 2017), which stimulate tourism and facilitate recreation. Thus, highland habitats are frequently managed by federal laws under some level of protection to ensure these resources are used sustainably for human benefit (Grêt-Regamey et al., 2012). In North America, protected areas in highland habitats exceed the 17% recommendation of the Convention on Biological Diversity (Aichi, Target 11), and therefore serve as important refuges for terrestrial biodiversity in general (Elsen et al., 2018).

North American highland habitats span the extent of the continent (Fig. 1) in what is known as the North American Cordillera. The North American Cordillera joins the American Cordillera in South America to form a nearly continuous string of mountain ranges running along the western side of the two continents. In North America, highland habitats range from the arctic north in the Brooks and Alaska Ranges to the tropical Sierra Madre del Sur in southern Mexico, and cross the entire continent from the Pacific Coast mountain ranges that are in western North America to the Appalachian Mountains and Sierra Madre Oriental in eastern North America. The physical geography of these mountains plays an important role in influencing the distribution of biomes and biogeographical patterns among mountain ranges. Most of these mountains are oriented north-south, which leads to variation in the elevational range of highland biomes and the distributional range of associated species across latitude. Additionally, North American highlands comprise multiple isolated mountains or mountain ranges (such as the Cascades volcanic chain, or the Southern, Central and Northern Rocky Mountains), which leads to high species turnover (local endemism) across isolated montane habitats. Furthermore, these mountains formed at different intervals of time (Coney, 1972), which further influences the biogeography of highland species.

Fig. 1 Map of major highland areas and mountain biomes (Körner et al., 2017) in Canada, the United States and Mexico.

Major Highland Areas

Among the major North American mountain ranges, the Brooks Range is highest in latitude, sitting within the Arctic Circle in Alaska and Canada, where it began to form as early as ~145 million years ago (Mull et al., 1997). It spans nearly 1100 km in an east-west orientation, and its southern slope demarcates the northern limit of coniferous forest belts as they give way to arctic tundra. To the south, the Alaska Range in southeastern Alaska is one of the world's highest mountain ranges, with Denali surpassing all other mountain summits in North America with an elevation of 6190 m. The range stretches in an east-west orientation over 650 km and started forming ~144 million years ago (Ridgway et al., 2002) as part of tectonic plate collisions along the Alaska Range suture zone. It continues to experience frequent earthquakes as it overlays multiple active fault zones. With some of the harshest weather in the world (winds reaching 240 km per hour and temperatures as low as -70°C), it supports massive glaciers (>1100 m thick and >70 km long). The rapid loss of these glaciers due to climate warming appears to be a significant factor in the rise of sea level globally (Berthier et al., 2010).

The largest mountain range in North America is actually a complex of mountain ranges known as the Pacific Coast Range, which stretch 6100 km north-south along the edge of western North America in Canada, the United States, and Mexico. It includes the St. Elias Mountains in southeastern Alaska, the Canadian Coast Range, the Olympic Mountains of Washington state, the Oregon and California Coastal Ranges, the Peninsular Range in southern California and Baja California, and the Sierra Madre Occidental in Mexico. The mountains were initially formed by the accretion of island arc terranes (starting as early as ~325–350 million years ago), but significantly uplifted during the Laramide orogeny (~80 million years ago) that was initiated by subduction of the Farallon and Kula plates under the edge of the North American plate boundary as it moved slowly westward (Dickinson et al., 2009). The Pacific Coast Range encompasses a broad range of habitats, but perhaps the Sierra Madre Occidental is most distinctive (and therefore is treated separately below), with its species-rich pine-oak forests offset by desert and tropical deciduous forest at low elevations. Many of the mountain ranges within the Pacific Coast Range experienced differential rates of uplift through time, and subsequent volcanic activity. The Sierra Madre Occidental had several periods of uplift (in the Eocene, Oligocene, and Miocene), with the most recent volcanic activity occurring during the Pliocene in the Trans-Mexican Volcanic Belt in the south (Ferrari et al., 2007).

The youngest mountain range in North America is the Cascade Range, with most of the modern volcanoes forming less than 4 million years ago, and highest formed as recently as 100,000 years ago (Cheney, 2016). A complex of 20 major volcanoes spans 1100 km from southern British Columbia to northern California. The volcanic arc starting forming 37 million years ago as the Juan de Fuca plate began subducting under the North American Plate (McKenzie and Parker, 1967). The 12 largest volcanoes demonstrate a history of glaciation, and several support large modern glaciers. Coniferous forests dominate lower elevation habitats in most of the Cascade Range, although there is a strong rain shadow effect and habitats are typically dry to the east. The higher elevations support subalpine and alpine biomes.

The Sierra Nevada begins at the southern terminus of the Cascade Range in northern California and runs south for an additional 640 km south to the Transverse Range in southern California. Formed by the subduction of the Farallon plate and accretion of island arcs, the Sierra Nevada began uplifting 155 million years ago, and may have provided high elevation habitats throughout

its early history (House et al., 1998). Another period of uplift began 10–20 million years ago, associated with the crustal extension of the Basin and Range province, and continues to uplift the mountain range today (Huber, 1981). The range supports extensive contiguous habitat above 2500 m elevation, forming subalpine, and alpine biomes. Lower elevation habitats support coniferous forests, and a rain shadow effect to the east creates high desert habitat in the Great Basin.

Moving eastward into the interior of North America, the Rocky Mountain chain stretches 4800 km from northern British Columbia to New Mexico. It is a series of discontinuous mountain ranges of distinct origin, often grouped into the northern, central and southern Rocky Mountains. The modern mountain ranges were formed primarily during the Laramide orogeny (80–55 million years ago), though the Rocky Mountains overlay older mountains formed as early as 300 million years ago (English and Johnston, 2004; Dickinson et al., 1978). The mountains support substantial subalpine and alpine habitat throughout their extent, with coniferous forest largely dominating low elevation habitats. A strong rain shadow effect defines the Great Plains to the east of the Rocky Mountains, but it is also notable that the Great Basin to the west of the southern and Central Rocky Mountains is predominantly a high desert biome.

Continuing east, the Appalachian Mountains run north-south from southeastern Canada to the southeastern United States for approximately 2400 km. Most of the range is relatively low-lying, around 900 m in elevation, but the mountains in North Carolina reach over 2000 m in elevation. The Appalachian Mountains are an ancient mountain range, having formed 480 million years ago (Gibson, 1970) during plate tectonic activity associated with the formation of the supercontinent Pangaea. Periods of nearly complete erosion and subsequent uplift appear to have characterized its history through time, with a recent uplift in the mid-Miocene ~11–16 million years ago (Poag and Sevon, 1989). The Appalachian Mountains support a diverse set of biomes, including temperate rainforest and bogs, as well as a coniferous forest belt that extends to high elevations. Much of the low elevation habitat supports the deciduous broadleaf and mixed forest biome characteristic of the eastern United States and southeastern Canada.

Going south along the east coast of Mexico is the Sierra Madre Oriental, which is at the same longitude and formed from the same Laramide orogeny (80 million years ago) that uplifted the Rocky Mountains (Guzmán and de Csema, 1963; Fitz Diaz et al., 2017). It spans approximately 1000 km, from the Rio Grande in the state of Coahuila south to Hidalgo, where it meets the Trans-Mexican Volcanic Belt. With some summits reaching 3700 m elevation, the Sierra Madre Oriental supports a high diversity of endemic species found in a pine-oak forest biome and cloud forest. Lower elevation habitats are often xeric. The Mexican Plateau lies to the west of the Sierra Madre Oriental, averaging >1000 m in elevation, and is characterized by deserts and shrublands. The Gulf Coastal Plain lies to the east with subtropical to tropical forest and grasslands.

Farthest to the south, the Sierra Madre del Sur runs 1000 km west to east in southern Mexico, from the state of Michoacán through Guerrero to Oaxaca, ending at the lowland Isthmus of Tehuantepec. It starting forming as part of the Laramide orogeny (~80 million years ago), but most significant uplift occurred in the Late Paleocene to Miocene epochs (56–23 million years ago) as a result of interactions among the North American, Farallon, and Caribbean plates (Cerca et al., 2007). High elevation habitats (with summits reaching >3700 m elevation) support pine-oak forest and exceptional species endemism, while low elevations support tropical dry forest habitat.

Biotic Challenges and Biotic Zones in Highland Habitats

Katabatic and föhn winds can accelerate to hurricane force, rushing downslope over mountain backbones, to tear plants from the ground. Encountering a swath of full grown trees, uprooted alive and tossed again to the ground in a windthrow, draws a vivid image of the volatility and intensity of abiotic stresses in highland habitats. While harsh wind, rockslides and avalanches are among the abiotic factors influencing the distribution of life in highland habitats, they are relatively minor compared to the important roles of temperature, precipitation, solar radiation, and oxygen concentration. Temperatures decline with elevation, and low mean temperatures near mountain summits limit the annual productivity of plant life and activity of animal life. Additionally, high elevation habitats frequently experience broad daily temperature variation, which requires behavioral, physiological or morphological specialization to these environments. Precipitation is typically greater in highland habitats relative to low elevation habitats, though it often varies seasonally (and can be effectively drier in summer periods). Coupled with cooler temperatures, high elevation precipitation often forms frost or snow. In northern mountains, snow can persist for 9 months of the year, or in some cases never disappear, eventually compressing into glacial ice. This reduces annual growth opportunities, as many organisms wait for snow-free conditions to start growing. In southern tropical mountains, mid-elevation habitats experience nearly constant cloud cover at the level of the canopy trees, creating the misty wet cloud forest environment. This alters the spectral bandwidth of penetrating sunlight and the reduced light quality requires a corresponding shift in absorbance spectra of plants conducting photosynthesis (Reinhardt et al., 2010). Aside from cloud interference, the quality of sunlight shifts with elevation in mountain habitats as solar ultraviolet (UV) radiation generally increases (Blumthaler et al., 1997). UV radiation has been linked to DNA damage in plant and animal tissues, and biologically active pigments are often used to absorb or reflect harmful UV rays (Barnes et al., 1987; Sommaruga, 2001). Finally, atmospheric oxygen levels decline with higher elevation, roughly at a linear rate, such that oxygen levels are 50% of their value at sea level at 5500 m elevation (Peacock, 1998). Some animals and plants have evolved strategies to enhance oxygen uptake and limit hypoxia, such as the deer mouse which has altered globin molecules to have greater affinity for oxygen molecules (Storz et al., 2009).

This range of environmental conditions and physiological challenges has created unique habitats and patterns of biodiversity in highland areas. Low to mid-elevation highland habitats in North America encompass nearly the entire diversity of North American biomes. They are typically extensions of habitats in the immediate vicinity of the highlands, though it should be noted that

mountainous regions often influence these habitat types by capturing precipitation from air flow across the mountain (orographic precipitation) and producing rain shadows on the leeward side of the mountain that lead to desertification. Major components of low to mid-elevation montane habitats in North America include temperature deciduous and evergreen forests, tropical rainforest and dry forest, and Mediterranean forest, woodland, and scrub habitats. In contrast, high elevations give rise to several unique biomes that are only found in highland habitats, including cloud forest, subalpine forest, and alpine tundra and grasslands.

Cloud Forest Biome

In subtropical and tropical settings, highland environments can be characterized by a unique evergreen montane forest habitat known as the cloud forest biome. Clouds form at the level of the forest canopy and persist throughout the day, and across seasons, providing wet and cool conditions. A significant portion of the precipitation in this biome is created by the condensation of fog on plants, but the persistent cloud cover also reduces evapotranspiration. These saturated environments have reduced decomposition rates, reduced mineralization and increased soil acidity. Another consequence of steady cloud cover is reduced solar radiation, which limits the photosynthetic potential of plants. These abiotic factors provide unique challenges and opportunities to plant life in these environments. While plant species characteristic of cloud forests vary between regions, tree ferns, *Podocarpus*, and arbo-real bromeliads are often found in Mesoamerican cloud forests. In some high elevation cloud forests, particularly on more isolated mountains, elfin forest may occur, with stunted trees and extensive moss and epiphyte growth. Endemism of plant and animal life is exceptional in cloud forest habitats (Hamilton et al., 2012; Webster et al., 1995), even though they comprise less than 1% of the total area in global forest habitats.

Subalpine Biome

In many North American highland habitats, the upper elevational distribution of trees forms the subalpine biome. Coniferous fir, hemlock, spruce and pine trees are characteristic of many North American subalpine habitats. As they near their upper elevational limits ("treeline"), these windblown trees become dwarfed and twisted into krummholz forms, often growing horizontally across the ground and in clumps in response to wind. Subalpine habitats include the transition from closed "timberline" forest to this treeline. Subalpine biomes also include subalpine meadow and bog habitats, which are frequently irrigated throughout summer months by snowmelt from higher elevations and may have riparian areas with willow species. The climate is harsh in this biome, with heavy precipitation in the form of snowfall and low mean temperatures from early fall to late spring. The resulting growing season is short and restricted to summer months, and many subalpine species have evolved to be long-lived and to develop slowly. Subalpine and alpine communities often share species, but the subalpine habitats have a greater diversity of species, including montane species reaching their distributional limits (Billings, 1974).

Alpine Biome

Among the biomes encountered in highland habitats, the alpine biome is the smallest in overall area and the lowest in overall species diversity, but notable in having a distinct endemic fauna and flora (Stebbins and Major, 1965). It is characterized by treeless habitat, cold daily and annual temperatures (the annual mean temperature at which trees fail to grow is 1.5–3°C), heavy snowfall and short growing seasons, and often high elevations (in some cases reaching as high as 3000 or 4000 m above sea level). This biome is perhaps the most dynamic, having undergone dramatic climatic fluctuations, distributional shifts, and rapid community assembly subsequent to the last glacial maximum (Gillespie and Zehfuss, 2004; Woolfenden, 2003). This dynamic pattern has repeated over semi-regular time intervals during the climatic cycles of the Pliocene and Pleistocene epochs.

There are a variety of distinct habitat types within the alpine biome of North America. Perennial grasses, sedges and forbs frequently characterize the wind-swept areas and alpine meadows. These plants typically grow close to the ground and have more below-ground than above-ground biomass, which is important in storing energy over winter. While windswept habitats are relatively barren, alpine meadows have dense grass and forb vegetation, and also include prostrate shrubs. Alpine rock gardens form on well-draining slopes (often gravel beds or sandy soils) with cold-specialized succulents and cushion plants. These plants are compact and low-growing to avoid wind damage, and have thickened leaves, matted growth forms and tap roots to help extract and retain water in this dry microhabitat. The flowers of these plants are often large and showy relative to the plant size, and are attractive to a diverse set of insect pollinators.

North American Highland Habitats Through Time

Global climate has cooled dramatically since the Paleogene period (65–23 MYA), leading to expansion of polar ice, the development of continental and alpine glaciers, and a shift from tropical to temperate biomes at high latitudes (Gingerich, 2006). Although highland environments existed in many parts of the world during the Paleogene (Mani, 1968), it is unclear whether the abiotic conditions in these environments created the diversity of biomes found in modern mountains. In particular, the distinctive alpine biomes may not have characterized high elevation habitat Paleogene mountains, unless those mountains were much higher in the

past than at present. When did modern highland biomes develop in North America and what is the earliest age for the origins of endemic montane organisms?

Furthermore, how did subsequent climate change influence the distribution and connectivity of highland biomes through time? Fluctuations in past global climate, in the form of warming and cooling trends and shifts in global circulation and precipitation, are evident in a variety of global geological, chemical and paleontological records. Global cooling trends ("icehouse conditions") increased in frequency and severity from the Miocene and Pliocene into the Pleistocene, and a cyclical pattern of cooling and warming now characterizes long-term global climate (Lisiecki and Raymo, 2007). Alternating glacial (stadial) and interglacial (interstadial) periods are thought to be caused by orbital forcing (changes in the tilt of the Earth's axis; Hays et al., 1976), although there is debate about this relationship (reviewed in Lisiecki and Raymo, 2007). The highest resolution indicator of the frequency, duration and intensity of global temperature changes is dissolved oxygen isotopic variation preserved in Northern Hemisphere ice cores (Andersen et al., 2004; Jouzel et al., 1987) and the fossil remains of foraminifera preserved in oceanic sediments (Lisiecki and Raymo, 2005). The repeated global cooling trends observed in these records are highly correlated and nearly synchronous with the development of massive continental and alpine glaciers (Benson et al., 1997), as well as the timing of related landform transformation (Kaufman et al., 2004), sea-level depression (Herbert et al., 2001), and dramatic regional shifts in plant and animal distributions (Bradshaw, 1999). Global records have been combined and used to model atmospheric temperature over the last 5.3 million years (Lisiecki and Raymo, 2005), with high precision over the last 1 million years (Bintanja et al., 2005). This record is useful for identifying the timing, duration and intensity of worldwide glacial phases over the both Pliocene and Pleistocene epochs. However, it is not clear whether global temperature records from these sources translate into climate events at a regional scale in a given mountain range (Herbert et al., 2001, 2002). Some scientists have argued that the timing of glacier growth and retreat in highland habitats is offset from these global records by local circulation patterns (Bischoff and Cummins, 2001; Winograd et al., 1992; Winograd, 2002).

These glacial-interglacial transitions have had profound effects on animal and plant distributions (Comes and Kadereit, 1998; Hewitt, 1999; Bradshaw, 1999), as well as the physical geography of different regions. While many highland habitats in North America are currently isolated and environmental conditions limit the dispersal of highland organisms, these environments reorganized during glacial phases and connectivity to other mountains may have increased. While some authors have argued that glacial stage environments lead to the expansion of highland biomes (Chabot and Billings, 1972; DeChaine and Martin, 2004), it is not clear whether highland organisms went through population expansion or contraction during these episodes as they were displaced by glacial ice. By developing information on the timing and geographical extent of glaciations in highland habitats, it may be possible to constrain the temporal intervals of dispersal from other mountain ranges, as well as the intervals of potential population size changes in response to past climatic events.

While the geology of the North America has been studied since the 19th century, there continues to be debate about the paleoelevation of mountain ranges and how elevation has changed through time (Cecil et al., 2006; Mulch et al., 2006; Molnar and England, 1990). In this section, we review the literature on the timing of mountain building, estimates of paleoelevation in North America, and subsequent climate history for several key mountain ranges, in an attempt to provide age constraints on the origin of subalpine and alpine highland habitats.

Sierra Nevada Mountains

The Sierra Nevada began developing as a continental arc during the late Triassic period (Ducea, 2001), but the extent of uplift at that time remains unclear. Previous interpretations of sediment discharge and erosion, which implied a rapid uplift of the Sierra Nevada during the Miocene epoch, have been criticized due to concurrent glacial processes and their importance on measured rates of sediment discharge and erosion (Molnar and England, 1990). More recent attempts to infer the age and paleoelevation of the Sierra Nevada have relied on isotopic data from minerals and volcanic glass. These studies suggest that topographic surfaces similar to modern surfaces were present at least 60 million years ago (Cecil et al., 2006; House et al., 2001), and that a rain-shadow effect similar to the modern one has been in place over the last 12 million years (Mulch et al., 2008; Poage and Chamberlain, 2002). Thus, high elevation habitat has existed for at least 12 million years. The White Mountains of California, lying east and at one point connected to the Eastern Sierra Nevada, also reached high elevations in the period from 12 to 6 million years ago (Stockli et al., 2003). The Sierra Nevada continued to increase in relief from 10 to 3 million years ago, which is evident in increased incision rates in multiple river canyons (Stock et al., 2004).

While paleoelevation in the Sierra Nevada has been high since the Miocene, it is unclear whether these high elevations provided conditions suitable for highland organisms. While available data do not provide a clear upward bound for the appearance of cold climatic conditions at high elevations, extensive evidence of recent, repeated alpine glaciation in the Sierra Nevada is represented in a variety of geological features, including moraine deposits, erratic boulders, U-shaped valleys, and glacial sculpting (Guyton, 1998; Gillespie and Zehfuss, 2004). These geological features provide strong support for the existence and geographical extent of Pliocene-Pleistocene glacial events over the last 3 million years. Furthermore, the downstream drainage of glacial sediments ("rock-flour") and deposition of pollen in nearby lakes provide high resolution estimates of the onset, duration and retreat of alpine glaciers (Benson et al., 1997; Bischoff and Cummins, 2001), although these data are mostly limited to recent geologic history (<200,000 years B.P.).

There are slight differences from the global climate average, in terms of the timing and resolution of glacial activity, evident in recent paleorecords from the Sierra Nevada (Bischoff and Cummins, 2001; Gillespie and Zehfuss, 2004). Most importantly, these

data indicate repeated growth and recession of alpine glaciers during major glacial phases, suggesting that glacial environments were not stable and were influenced by local climate shifts. The importance of short-term distributional shifts has been well studied using plant pollen and macrofossil remains (Smith and Anderson, 1992; Woolfenden, 1996, 2003; Thompson and Anderson, 2000; Davis, 1999; Serceij and Adam, 1975), as well as fossilized midges (Porinchu et al., 2003, 2007). Highland species may have fluctuated in abundance and distribution during these short-term climate oscillations, and so the hypothesis of expanding highland habitats during glacial phases or long stable geographical distributions requires testing with further evidence.

Rocky Mountains

Similar patterns apply to the Rocky Mountains, but they are significantly different in having a much longer history of high elevation habitat. The uplift of the Rocky Mountains during the Laramide orogeny (80–55 million years ago) is thought to have generated considerable topographic relief (>2 km in elevation) that affected continental weather patterns (Bird, 1984; Dettman and Lohmann, 2000b). Some studies have suggested that paleoelevations were even higher (>4000 m on average), reaching elevations beyond those seen in the present day (Mulch et al., 2004). As recently as the Miocene (Wolfe et al., 1998), paleoelevations are thought to have remained near modern levels and could therefore have supported permanent snowfields (Dettman and Lohmann, 2000a; Norris et al., 1996). This would suggest that subalpine and alpine biomes were present in the Rocky Mountains for at least 23 million years, or perhaps even longer. However, the presence of permanent snow and such high elevations through time remains under debate (Fricke and Wing, 2004).

Appalachian Mountains

Reconstructed climates during the Paleozoic (255 million years ago) suggest the Appalachian Mountains may have been as high as 4500 m during its early history (Fluteau et al., 2001), providing significant relief that may have supported modern montane biomes. However, geological studies have demonstrated a long history of sediment erosion that is consistent with gradual decline in the elevation of the mountains through time (Gibson, 1970), with a lack of significant tectonic uplift for >100 million years. This suggests the mountains have lacked substantial high elevation habitat for some time, as they currently reach maximum elevations of 2000 m and erosion has proceeded at a rate of 27 mm per kyr (Gallen et al., 2013). Although more recent studies have shown that the Appalachian Mountains have gained elevation in subsequent periods, for example in the mid-Miocene (Poag and Sevon, 1989; Gallen et al., 2013), the elevational uplift only resulted in 100–150 m elevation gain (McKeon et al., 2014).

Biodiversity and Biogeography of North American Mountains

Biodiversity patterns are often quantified in terms of species richness (the number of species) and evenness (the richness weighted by the abundance of each species), although there are other measures that weigh functional diversity (accounting for ecological or morphological variation), phylogenetic diversity (accounting for the evolutionary distinctiveness of species), and endemism (the number of unique species found in that region). The highlands of North America are considered global biodiversity hotspots based on representation of distinct habitat types (Olson and Dinerstein, 1998), and many rank highly in terms of species richness and/or endemism (Pimm et al., 2014; Ricketts et al., 1999). Endemism is particularly high in unique biomes represented in mountain ranges, for example in the alpine flora of the Sierra Nevada (Rundel, 2011), or the birds of cloud forests of Mexico (Fjeldså et al., 2012). Southern mountain ranges, particularly the highlands of Mexico, are exceptionally rich in numbers of species compared to more northern highland areas in North America (Table 1). In part, this trend reflects the latitudinal diversity gradient, a well-known phenomenon of global biodiversity patterns where species richness exhibits a general trend towards decreasing species diversity toward the poles (Gaston, 2000).

Biogeography is the study of species distributions in space and time, and includes research on the evolutionary history and ecology of species. There are three main biogeographical sources for highland species in North American mountain regions. The first involves dispersal from a similar biome in a nearby mountain range. Under this model, species should be closely related among mountains, with evolutionary distance increasing with geographical distance and/or the age of mountains (Chabot and Billings, 1972; Kimball et al., 2004; Brown, 1971). The second model involves dispersal over long distances from similar biomes found in other parts of the world. For example, arctic and alpine environments are similar, and some plants and animals inhabit both biomes, in some cases stretching in distribution from Eurasia to North America (Billings, 1973; Packer, 1974). Such long range dispersal might be facilitated by climate fluctuations through time, when favorable conditions are episodic and allow dispersal over longer distances than currently seem possible. Third, highland species might have evolved from species inhabiting lower elevation habitats in the same mountain range, in a process of ecological diversification across different montane biomes. The retention of species in a particular highland area has been associated with the rate of past climate change and dispersal ability of species (Sandel et al., 2011), where those habitats undergoing the most change have lower diversity and poorer representation of low dispersal organisms. Once established in a given mountain range, lineages can evolve to have multiple endemic species as diversification occurs due to (1) multiple colonization events from an exogenous source, (2) geographical isolation within the mountain range (allopatric or peripatric speciation) due to geographical barriers or climate fluctuations, and/or (3) sympatric or parapatric speciation.

Table 1 Species richness in major North American highland areas

The Alpine Biome in North America

There is considerable evidence that alpine species have dispersed among mountain ranges in temperate North America during glacial climate fluctuations, and that their distributional patterns relate to habitat suitability and dispersal ability (Major and Bamberg, 1967). For example, highly dispersive alpine taxa moved between the Rocky Mountains and Sierra Nevada Mountains by crossing the Great Basin during glacial periods, including plants (Chabot and Billings, 1972; Kimball et al., 2004), mammals (Brown, 1971), birds and butterflies (Wilcox et al., 1986). Such distributional patterns have been supported with genetic studies of population and species relationships (Schoville and Roderick, 2009; Nice and Shapiro, 2001; Schultheis et al., 2012; Schoville et al., 2011). Less dispersive taxa do not show this pattern, instead showing relationships in a north-south orientation along the Sierra Nevada-Cascades Range, or the Rocky Mountains-Northern Cascades (Charlet, 2007; Fites-Kauffman et al., 2007; Galbreath et al., 2009; Shafer et al., 2010). For those taxa with extremely limited dispersal abilities, multiple alpine species have evolved within a mountain range as a consequence of glacial climate fluctuations and geological barriers (Schoville and Roderick, 2010; Rovito, 2010; Schoville et al., 2012). These studies suggest that dispersal, rather than ecological divergence from low elevation species, is the principal factor governing the biogeography of alpine species. However, there are a few notable cases where ecological divergence has occurred across montane and alpine biomes (Rovito, 2010; Rubidge et al., 2014), perhaps as a result of parapatric speciation. Very large mountain ranges, with extensive topographic variation, distinctively show such a pattern of extensive local species diversification (Xing and Ree, 2017). Some examples of species whose histories have been reconstructed using genetic data are shown in Fig. 2.

Broad-scale biogeographical studies have shown that alpine species are frequently closely related over vast distances (Mani, 1968), spanning isolated mountain ranges in the Northern Hemisphere (Kadereit et al., 2008; Hultén, 1937). As many of the diverse alpine species assemblages are products of recent species radiations (Hughes and Atchison, 2015), this raises the question of whether alpine lifeforms have arisen from a common source. One of the more interesting hypotheses suggests that uplift of the Himalayan Mountains and Tibetan Plateau (~40 million years ago; Renner, 2016), following the collision of the Indian subcontinent with the Asian continent 52–55 million years ago, may have led to the evolution of alpine specialists in many taxonomic groups (Favre et al., 2016). The emergence of high elevation habitats during a period of warm global temperatures would have isolated such species until global cooling events began, following the first Antarctic glaciation 34 million years ago. The onset of global climate cooling, and particularly the frequent and extensive glaciation events of the Pliocene and Pleistocene epochs (3 million years ago to the present), subsequently allowed dispersal to distant mountain ranges in Eurasia and across the Bering Land Bridge into North America (Zhang et al., 2014; Wang et al., 2016). However, a competing model is for the highland habitats in North America (i.e., the Rocky Mountains) to have served as a cradle for the evolution of alpine specialists during the Laramide orogeny (80–55 million years ago), with subsequent dispersal towards the mountains in Eurasia (Ebersbach et al., 2017). Both cases are supported by empirical data, and it remains possible that other early mountain ranges served as cradles for the evolution of alpine ecotypes.

Mexican Cloud Forests

Cloud forests occur at intermediate elevations in the Sierra Madre Oriental, northern highlands of Oaxaca, and in some portions of the Sierra Madre del Sur of Oaxaca, Mexico. They form a band between the tropical forest or pine forest below and the montane pine-oak forest above. Cloud forests contain a mix of north temperate floral elements, such as oaks (*Quercus*) and sweetgum (*Liquidambar*) and elements such as *Podocarpus* that originated in South America. Genetic and paleobotanical data show that *Podocarpus* has been present in Mexican forests since the Miocene, as has *Liquidambar* (Graham, 1999; Ornelas et al., 2010; Ruiz-Sánchez and Ornelas, 2014). In the north, cloud forests occur as sky islands on isolated mountains, such as in the emblematic El Cielo Biosphere Reserve, while their distribution becomes somewhat more continuous to the south. Their association with cloud formation confines

Fig. 2 The alpine biome is characterized by species that were able to disperse among mountain ranges during the last glacial period, as well as those with limited dispersal ability that diversified within mountain ranges. The butterflies (A) *Colias behrii* and (B) *Parnassius behrii* are recently derived endemic species in the Sierra Nevada, closely related to species found in the Rocky Mountains. (C) A view of alpine and treeline habitats in the Cathedral Range of Yosemite National Park. (D) Ice crawlers, *Grylloblatta* sp., are wingless insects that have diversified into a complex of 7–8 species in the Sierra Nevada.

them to a narrow elevational belt, which is broken in many places by lower elevation valleys with tropical or xeric vegetation. This elevational belt likely moved upward during interglacial periods and downward during glacial periods, resulting in expansions and contractions of cloud forest habitat. Such changes in cloud forest extent have resulted in demographic fluctuations within wide-ranging species including the Maquique tree fern, a typical cloud forest taxon (Ramírez-Barahona and Eguiarte, 2014). In other species, including some with relatively high dispersal capacity such as jays (*Aphelacoma*), glacial cycles have resulted in lineage divergence and cryptic allopatric speciation between cloud forests in different regions (Venkatraman et al., 2018). Because of their strong dependence on cloud water, different combinations of past temperature and precipitation changes could have resulted in less predictable patterns of distribution change compared to other vegetation types.

Cloud forest fragmentation and expansion in response to climatic changes have produced complex patterns of genetic diversity across wide-ranging species (Ornelas et al., 2010; Ramírez-Barahona and Eguiarte, 2013). Past distributional changes and fragmentation in cloud forest have likely resulted in repeated events of allopatric speciation in organisms with lower dispersal ability. This is especially likely in the case of organisms that make extensive use of arboreal bromeliads (strongly tied to cloud water deposition), which provide moist microenvironments during dry periods. Lungless salamanders (family Plethodontidae) are diverse in Mexican cloud forests (Fig. 3), and many species use arboreal bromeliads as daytime refugia (Wake, 1987). Most cloud forest salamander species are narrowly endemic to small regions or even single mountaintops, with sister species found in adjacent mountain ranges (Rovito et al., 2013; Rovito and Parra-Olea, 2015). In addition to the many likely cases of allopatric speciation in this group (Rovito, 2017), strong elevational gradients in the Sierra Madre Oriental, highlands of northern Oaxaca and other areas have provided opportunities for parapatric speciation between cloud forest and adjacent vegetation types. In the Sierra de Juárez of Oaxaca, for example, three pairs of sister species of salamanders occur, with one species found in bromeliads in the cloud forest and its sister species found at higher elevation in montane pine-oak forest. This pattern suggests that species formation, likely involving selection for bromeliad use in the cloud forest, could have led to parapatric speciation across the boundary between cloud forest and pine-oak forest over short timescales (Pleistocene) (Rovito and Parra-Olea, 2016; Rovito, 2017). Although less studied than vertebrates and vascular plants, cloud forest insects such as beetles of the family Passalidae have likely responded to distributional changes in cloud forest in similar ways to salamanders, with repeated events of dispersal and divergence between adjacent montane regions; such a pattern has been found in the cloud forests of Central America (MacVean and Schuster, 1981).

Conservation of North American Highlands

Mountain ranges are under considerable threat of habitat loss, habitat degradation, and climate change (Payne et al., 2017). Habitat loss and degradation result from resource extraction (forest products and mineral ores), agricultural intensification and residential

Fig. 3 Salamanders in the cloud forest biome of the Sierra Madre Oriental and highlands of Oaxaca have diversified among isolated forest patches. (A) Cloud forest habitat showing extensive growth of arboreal bromeliads and other epiphytes. (B) *Pseudoeurycea saltator*, a cloud forest endemic typically found in arboreal bromeliads. (C) *Thorius arboreus*, one of the smallest species of salamanders, reaches a maximum of 20 mm snout-vent length and is found in bromeliads in the cloud forest of the Sierra de Juárez, Oaxaca. (D) *Chiropterotriton cieloensis*, a salamander endemic to the cloud forests of the El Cielo Biosphere reserve in Tamaulipas, Mexico. El Cielo (a sky island) and nearby forest patches represent the northernmost extent of cloud forest habitat in North America.

development. While these land use changes primarily influence unprotected mountain habitats, even pristine mountain habitats in protected areas are undergoing dramatic changes due to global warming. Over the last century, U.S. national parks have seen a 1.0°C increase in average temperature (Gonzalez et al., 2018). In at least a third of all mountains globally, climate shifts are predicted to lead to declines in available habitat for montane biomes due to the reduction of surface area available at higher elevations on mountains (Elsen and Tingley, 2015). These changes not only result from temperature increases, but also from precipitation changes and the discordance between temperature and precipitation shifts (McCain and Colwell, 2011). This is alarming, as montane habitats not only protect high levels of biodiversity, but have also served as refuges for diverse species of biota during past climate change. Highland regions are also particularly rich in intraspecific genetic diversity (Stralberg et al., 2018). Importantly, changes to highland biomes are occurring rapidly and we still lack basic knowledge of the biodiversity of North American highlands, the function and value of their diverse ecosystem services, and the resiliency of montane ecosystems to ongoing change (Payne et al., 2017).

Among the North American highland biomes, Mexican cloud forest biomes are considered particularly vulnerable to global climate change (Still et al., 1999; Ponce-Reyes et al., 2012), and many of the species found in these habitats have limited physiological tolerance for temperature extremes or dry conditions outside the mean conditions of these habitats (Pounds et al., 1999; Nadkarni and Solano, 2002). These forests are also threatened by the deforestation of lower elevation tropical forests (Lawton et al., 2001), which reduce the cloud layer and raise temperatures in upland cloud forest habitat. Alpine and subalpine biomes, in contrast, may be more stable to shifting temperatures due to topographical complexity at local scales (Graae et al., 2018). For example, certain habitats such as mountain streams appear to be changing relatively slowly (Isaak et al., 2016). However, incremental temperature change may be less significant to these biomes than the threat of declining snowpack (Mote et al., 2005), which increases the exposure of alpine organisms to extreme temperature fluctuations (Choler, 2018), increases the aridity of these habitats, and raises the risk of fire (Camac et al., 2017), and alters mountain hydrology (e.g., heavy rainfall instead of snowfall increases flood events and erosion).

Abstract

An understanding of the heterogeneity, or nonrandomness, in the distribution of species on Earth is one of the central goals in the ecological sciences and constitutes the collective science of Biogeography. This multidisciplinary branch of science incorporates elements from widely disparate disciplines such as biology, ecology, geography, remote sensing, physical and climate sciences and studies all aspects of the adaptations of an organism to its environment, considering systematically the origins, migrations and associations of living things. Mountain systems provide ideal ecological laboratories to understand the biogeography of plants and animals as they present a large variety of environmental conditions across their elevational gradients, thereby hosting a great variety of life forms over short distances. This is particularly true for the mountain systems of the tropics which harbor some of the world's finest biodiversity hotspots. In this article, we describe briefly the biogeography of the 12 major mountain ranges of South Asia, which together form the backbone of the economy and biodiversity heritage of their respective countries. These majestic mountains play a pivotal role in determining, regulating and even modifying overall climate system of continental Asia, including the middle-east and parts of Europe and Russia. These act as reservoirs of unparalleled natural resources, glaciers and rivers systems supporting a major fraction of the human population

in the continent. A deeper understanding of the biogeography and natural heritage of these mountains is critical to their science-based conservation and for sustainable development in these remote regions with fast depleting resources.

Introduction

Biogeography is the collective science that incorporates elements from widely disparate disciplines, with a unified aim towards understanding the distribution of plants and animals. It studies all aspects of the adaptations of an organism to its environment, systematically considering the origins, migrations and associations of living things. Hence, it aims to synthesize data from non-biological (geology, geography, climatology and meteorology) and biological (biology, taxonomy, genetics, and physiology) disciplines. Biogeographical relationships can be understood only from an ecological perspective which examines the interactions between an organism and its environment. While historic biogeography attempts to understand the role of historic climate and paleogeography in determining current species distributions, modern biogeography includes current anthropogenic pressures as a major environmental variable influencing the distribution of plants and animals (Fig. 1 and Table 1).

Fig. 1 A Digital Elevation Map of South Asia, representing the major mountain ranges in the region.

Table 1 Distribution and associated environments of the major mountain ranges of southern Asia.

<i>Name</i>	<i>Country</i>	<i>Highest peak</i>
Aravalli Range	India	Guru shikhar: 1722 m
Eastern Ghats	India	Arma konda: 1680 m
Himalaya	India, Nepal, Pakistan, China, Bhutan	Mount Everest: 8848 m
Hindu Kush	Afghanistan, Pakistan	Tirich Mir: 7708 m
Karakoram	Pakistan, china, India	K2: 8611 m
Kirthar	Pakistan	Barugh Hill: 2151 m
Knuckles Mountain Range	Sri Lanka	Gombaniya: 1906 m
Pamir	Afghanistan	Kongur Tagh: 7649 m
Salt Range	Pakistan	Sakesar: 1522 m
Sulaiman Mountains	Pakistan, Afghanistan	Loe Nekan: 3578 m
Toba Kakar	Afghanistan, Pakistan	Takh-i-Sulaiman: 3449 m
Western Ghats	India	Anamudi: 2695 m

The Aravallis, India

The word Aravalli originates as a composite of two Sanskrit words “*ara*” + “*vali*” which translates to “*line of peaks*.” The Aravalli Range diagonally bisects the State of Rajasthan into a western arid region and the eastern semi-arid zone (Roy, 1990). The western zone, the Thar, is continued into a chain of arid zones up to the great Sahara desert. The hilly Aravalli terrain experiences frequent drought due to poor and delayed monsoons, high summer temperatures and limited water resources. The Northern Aravalli range in Delhi and Haryana has humid subtropical climate and hot semi-arid climate with very hot summers and cool winters. The maximum daytime temperature during the summer varies between 40 and 46 °C. During winter, it ranges between 1.5 and 4 °C. The Central Aravalli range in Rajasthan has an arid and dry climate. The Southern part of the range in Gujarat has a tropical wet and dry climate.

Rivers and Drainage

Three major rivers and their tributaries flow from the Aravallis, namely the Chambal, Sahibi and Loni. The Chambal and Sahibi rivers are tributaries of the Yamuna, while the Loni River flows into the Rann of Kutch. The north-to-south flowing rivers originate from the western slopes of the Aravalli range in Rajasthan, pass through the southeastern portion of the Thar Desert, and end along the coast of Gujarat. West to north-west flowing rivers originate from the western slopes of the Aravalli range in Rajasthan, flow through semi-arid historical Shekhawati region and drain into southern Haryana.

Biodiversity

The natural vegetation of the area falls within the Northern Tropical Dry Deciduous Forest and Northern Tropical Thorn Forest types (Champion and Seth, 1968). The Aravalli Biodiversity Park has over 160 species of native plants. The following national parks, wildlife reserves, and forests lie in the Aravalli Range:

Delhi: Northern ridge biodiversity park, Yamuna biodiversity park, Neela Hauz biodiversity park, Sanjay Van, Sanjay Lake, Aravalli Biodiversity Park, Tilpath valley biodiversity park, Asola Bhatti Wildlife Sanctuary.

Haryana: Aravali Biodiversity Park, Madhogarh biodiversity park forest, Nuh Aravalli biodiversity park forest, Satnali biodiversity park forest, Tosham hills range biodiversity park, Masani barrage wildlife area, Matanhail wildlife area, Chhuchhakwas-Godhari wetland, Khaparwas Wildlife Sanctuary, Bhindawas Wildlife Sanctuary, Sarbashirpur, Sultanpur National Park, Bandhwari forest, Mangar Bani forest, The Lost Lake (Gurugram).

Rajasthan: Sariska Tiger Reserve, Ranthambore National Park, National Chambal Sanctuary, Phulwari ki Nal Wildlife Sanctuary, Sita Mata Wildlife Sanctuary, Todgarh-Raoli Sanctuary, Mount Abu Wildlife Sanctuary, Kumbhalgarh Wildlife Sanctuary, Bassi Wildlife Sanctuary, Jaisamand Wildlife Sanctuary.

Gujarat: Balaram Ambaji Wildlife Sanctuary, Jambughoda Wildlife Sanctuary, Jessore Sloth Bear Sanctuary.

The Eastern Ghats, India

The Eastern Ghats are a prominent topographic feature on the Indian Peninsula, comprising of a broken chain of hills that extend from Orissa to Tamil Nadu, crossing Andhra Pradesh and stretching from the southern tip of the peninsula to near Bhubaneswar. The range derives its name from the Hindi word *ghat*, which means “a series of mountains.” Eastern Ghats are spread over three states of India namely Orissa, Andhra Pradesh and Tamil Nadu. The Eastern Ghats can be broadly divided into Northern, Central

Table 2 Eastern Ghat classification.

<i>State</i>	<i>Division</i>	<i>District</i>	<i>Hill ranges</i>
Orissa	Northern Eastern Ghats	Pulbani, Kalahandi, Ganjam	Mahendragiri
Andhra Pradesh	Northern Eastern Ghats	Srikakulam East Godavari Vijayanagaram	Palakonda, Pathapatnam, Mandasa, Sompeta Addatigala, Rampachodavaram hills, and Bison hills Sal forest Manda forest, Peddakonda forest, Duggeru forest, Kurupam forest
Andhra Pradesh	Central part of Eastern Ghats	Visakhapatnam Krishna Kurnool Prakasam Mahaboobnagar Cuddapah Nellore Chittoor, Cuddapah	Galikonda hills, Sunkari metta, Anantagiri Kondapalli ranges Nallamala ranges Yerramala. Palakonda ranges Veligonda ranges Seshachalam, Lankamala Nagari, Kambakkam ranges.
Tamil Nadu	Southern Eastern Ghats	North Arcot South Arcot Salem Namakkal Dharmapuri Tiruchirapalli	Javadi hills Gingee hills Shevaroy hills, Kalrayan Kollimalai, Bodamalai, Nainamalai Melagiri hills Pachamailai

and Southern sectors (Table 2). Land use changes of the last 200 years have greatly altered the natural vegetation (Anupama et al. 2014).

The Eastern Ghats have a tropical monsoon climate. This region receives rainfall from both the South-West North-East monsoons. In the northern part, the annual rainfall ranges from 114.2 to 165 cm, indicating sub-humid climate, whereas in the central and southern parts, the mean annual rainfall ranges from 60 to 106 cm exhibiting semi-arid climate except in the hilly station peaks. Heavy winter rains coupled with 15 cyclonic storms per year typify the climate of the eastern portion, especially in the coastal plains. The mean temperatures in January range between 20 and 35 °C. The maximum temperature increases up to 46 °C during summer season. During the rainy season the relative humidity is quite high, up to 70–75%.

Rivers and Drainage

The major rivers are the Cauvery, Krishna, Godavari, and Mahanadi, whereas the minor rivers include the Bahuda, Vamsadhara, Nagavali, Indravati, Rushikulya, Sileru, Sabari, Gundlakamma, Poleru, Sagileru and Penna. All these rivers empty into the Bay of Bengal. The Godavari originates in Triambak near Nasik in the Western Ghats. The Vashista, Gautami, Tulya, Attreya and Bharadwaja rivers are branches of the Godavari river. It flows over a distance of 1465 km before reaching the Bay of Bengal. Godavari is also known as the “Ganges of the South” or “Dakshin Ganga.” It flows throughout the year in the south. The Cauvery River rises near Brahmagiri hills and is one of the biggest river systems of peninsular India. It flows over a distance of 805 km before reaching the Bay of Bengal.

Biodiversity

The common mammal species in Eastern Ghats are the Indian elephant, blackbuck, Asian palm civet, small Indian civet, Madras treeshrew, common grey mongoose, sambar deer, Indian crested porcupine, Indian bison, wild boar, common muntjac, Indian leopard, Bengal tiger, dhole, golden jackal, Indian giant squirrel, Indian hare, Asian house shrew, tufted grey langur, Indian flying fox, bonnet macaque, rhesus macaque, Bengal fox, smooth-coated otter, jungle cat, cheetal, Nilgai, Indian boar, striped hyena, Indian Wolf and the Indian mole-rat. The common avifauna include the Great Indian bustard, red-wattled lapwing, spot-billed pelican, blue peafowl, Indian pond heron, hoopoe, spotted owl, greater coucal, pied crested cuckoo, Oriental white ibis, Indian pitta, Indian paradise flycatcher, red-vented bulbul, red-whiskered bulbul, jungle babbler, painted stork, black-rumped flameback, brahminy kite, jungle myna, Indian spotted eagle, Indian vulture, and Malabar whistling thrush. The endemic fauna of the Eastern Ghats are the Jerdon's courser and grey slender loris. The rare geckos found here are the Indian golden gecko, granite rock gecko, Yercaud slender gecko. The other reptiles include Sharma's skink and snakes such as Gower's shieldtail snake, Shortt's shieldtail snake and the Nagarjun Sagar racer. In total, nearly 100 species of reptiles occur in the Eastern Ghats.

The Himalaya, Bhutan, China, India, Nepal, and Pakistan

The Himalaya constitutes an impressive crescent-shaped mountain range extending for over 2500 km from the south of the Indus Valley beyond Nanga Parbat in the west to Namcha Barwa in the east; spanning five countries (India, Pakistan, Nepal, China and

Bhutan). The word Himalaya means “abode of snow” in Sanskrit. Nine of the world’s 10 highest peaks are located here, including the tallest—Mt. Everest. The Himalaya contain the world’s third largest deposit of ice and snow on the planet, giving it a common name of “The Third Pole.” The Himalaya consist of four parallel mountain ranges: the Sivalik Hills on the south, the Lower Himalayan Range, the Great Himalaya, which is the highest and central range, and the Tibetan Himalaya on the north. The average summer temperature in the southern foothills is about 30 °C and the average winter temperature is around 18 °C. In the middle of the Himalayan valleys the average summer temperature is around 25 °C while the winters are really cold. And on the higher region of the middle Himalaya the summer temperature is recorded at around 15–18 °C while the winters are below freezing point. The climatic condition at region above 4880 m is below freezing and is permanently covered with snow. During the winter the snowfall is heavy while the summers are much more mild and temperate. The Himalayan Alpine climate varies according to the altitude. Local climate is also affected by topography: The leeward side of the mountains receive less rain while the well-exposed slopes receive heavy rainfall (Palazzi et al., 2013).

Rivers and Drainage

The Himalaya are drained by 19 major rivers, of which the Indus and the Brahmaputra are the largest, each having mountain catchment basins of about 260,000 km² in extent. Five of the 19 rivers, with a total catchment area of about 132,000 km², belong to the Indus system—the Jhelum, the Chenab, the Ravi, the Beas, and the Sutlej—and collectively define the vast region divided between Punjab state in India and Punjab province in Pakistan. Of the remaining rivers, nine belong to the Ganges system, and three belong to the Brahmaputra system. Glaciers also play an important role in draining the higher elevations and in feeding the Himalayan rivers.

Biodiversity

Stretched over an area of more than 4 million km², the region hosts parts of four Global Biodiversity Hotspots: the Himalaya Hotspot, the Indo-Burma Hotspot, the Mountains of South-West China Hotspot, and the Mountains of Central Asia Hotspot (Chettri et al., 2008). Of the estimated 10,000 species of plants in the Himalaya hotspot, about 3160 are endemic, as are 71 genera. Furthermore, five plant families are endemic to the region, the Tetracentraceae, Hamamelidaceae, Circaeasteraceae, Butomaceae and Stachyuraceae. The largest family of flowering plants in the hotspot is the Orchidaceae, with 750 species. Biogeographically, the Himalayan Mountain Range straddles a transition zone between the Palearctic and Indo-Malayan realms. Species from both realms are represented in the hotspot (Salick et al., 2009).

The Hindu Kush, Afghanistan and Pakistan

The Hindu Kush is part of the larger Hindu Kush Himalaya ranges, and spans Afghanistan and Pakistan, with few parts extending into Tajikistan and China. The Hindu Kush system stretches for around 966 km laterally, and its median width is around 240 km. It divides the valley of the Amu Darya to the north from the Indus River valley to the south. The eastern end of the Hindu Kush in the north merges with the Karakoram Range. Towards its southern end, it connects with the Spin Ghar Range near the Kabul River. Since the Hindu Kush separates one major climate zone of Asia from another, the range’s climate shows great variations. The mountains of Swat Kohistan are within the area of the rain-bearing summer monsoon winds, and most of the eastern Hindu Kush, as well as the Hindu Raj, rises up at the extreme western limit of monsoonal Asia. This region experiences rainy or snowy summers (from July to September) and dry winters. The central and western Hindu Kush, however, border the Mediterranean climatic zone, characterized by hot, dry summers and cold, wet or snowy winters (from December to early March).

Rivers and Drainage

Rivers that flow from the mountain system include the Helmand, the Hari and the Kabul River. The lower Sistan basin gets little rainfall (~50 mm per year) and the main source of water is the Helmand River which brings snow-melt water from the southern Hindu Kush. The smaller Khash, the Farah and the Arashkan (Harut) rivers bring water from the western Hindu Kush. The basin of these rivers serves waters the region west to Hindu Kush, but the flow in these rivers fluctuates severely and has been a historical problem for any settlement. Extreme and extended droughts have been common.

Biodiversity

Well-adapted species of wildlife are found throughout the mountains. The Siberian ibex, markhor (both wild goats), Marco Polo sheep, black bear, Himalayan brown bear and urial (another wild sheep) are common. Chitral valley wildlife shelter the rare snow leopard. The landscape is home to a considerable number of globally threatened mammal species, including the Himalayan lynx, blue sheep, wolf and musk deer as well as small mammals like the golden marmot. The rich birdlife of the mountains includes vultures, eagles, Tibetan snowcock, Himalayan snowcock and the bar-headed goose. The streams of the northern slope contain brown trout in abundance. From about 1300 to 2300 m, sclerophyllous forests are dominant with *Quercus* and *Olea* (wild olive);

from 2300 to 3300 m one finds coniferous forests with cedars, *Picea*, *Abies*, *Pinus*, and junipers. Steppe desert vegetation covers the landscape between 3300 and 3600 m.

Karakoram–Pamir, Afghanistan, India, and Pakistan

The *Karakoram Range* derives its name from the literal translation, “Black Gravel.” The range lies in the hinterland of Eurasia and is regarded as the central backbone of Tibet. It forms the second highest range of mountain systems in the world. This complex of mountain systems, spanning Central and South Asia, hosts the mighty Hindu Kush in the west, the Pamir to the northwest, Kunlun mountain ranges to the northeast and the Himalaya to the southeast. The convergence of several international borders (Pakistan, Afghanistan, China, Tajikistan and India) give this remote region a high geopolitical significance.

The climate of the region is characterized as semi-arid and continental in nature. The steep and long southern slopes are fed by monsoonal moisture from the Indian Ocean, but the shorter northern slopes are relatively dry. The lower and middle slopes are arid, with annual precipitation that rarely exceeds 100 mm. At higher elevations (>4900 m), snow is the only precipitation, however, snowfall in lower elevations is also not uncommon. At higher elevations (>5700 m), the average summer temperature remains sub-zero and elevations below that (3900–5700 m), mean summer temperature ranges between 0 and 10 °C. Rarefied air, intense insolation, harsh winds and considerable diurnal temperature ranges constitute the typical features of this region.

Rivers and Drainage

The northern boundary is drained by the Yarkand and Karakash rivers, while the southern boundary is drained by the Gilgit, Indus and Shyok rivers, separating it from the Himalaya range. The Karakoram itself serves as the watershed for the Indus (south) and Yarkhand (north) rivers. Seasonal thawing of huge glaciers supply water to river channels, often resulting in floods on the moister southern slope.

Biodiversity

Ranges of several ungulates, such as the Marco Polo sheep and the orargali, have shrunk to the point that breeding only occurs in the eastern Pamirs, with animals migrating to the western Karakorams. Wild sheep (*Ladakh urials*) thrive in the lower mountains of the east, while the rocky slopes are frequented by the Siberian ibex and the markhors. Large raptors like the Himalayan griffon, lammergeiers and golden eagles are also commonly spotted in the region.

Kirthar Mountains, Pakistan

Traversing along the western boundary of the Indian subcontinent, eastwards of Ornach Nal and Chaman, stands the Sulaiman and Kirthar mountain ranges in the country of Pakistan, in the Sindh and Balochistan provinces. The mountains span over 310 km towards the south from the Mula River (east-central Balochistan) to Cape Monze on the Arabian Sea, forming the demarcation between the lower Indus plains and Balochistan. Overall, the precipitation pattern of the region is very erratic, both spatially and temporally, with overall arid conditions. The discharge of streams and river oscillates rapidly between dry and peak flow levels. The sudden burst in flow results in heavy erosion, coupled with extreme and destructive flooding. Rain occurs mostly during summer monsoons in the months of June–September. The average temperature records ranges from 18.21 °C in January to 33.61 °C in May. Short-term climate data from Dureji, Balochistan, reflects an arid climate, with mean annual rainfall of 65 mm, along with an average monthly temperature range from 15 to 38.1 °C.

Rivers and Drainage

The primary drainage of the south Kirthar mountains are the Hab and Lyari rivers, while the northern part is drained by the Kolachi river, all draining into the Arabian sea.

Biodiversity

Kirthar National Park is one of the largest wildlife protection areas of Pakistan, housing an array of rare and indigenous flora and fauna within its extensive mountainous terrain. Mammals such as the Singh ibex (*Capra aegagrus*), Urial (*Ovis vignei*) and Chinkara (*Gazella bennettii*) are found here. Indian grey mongooses, hedgehogs and porcupine are among the other encountered species. The park also hosts several winter deciduous species of small trees and shrubs such as *Prosopis cineraria*, *Tamarix aphylla*, *Lycium shawii*, *Salvadora oleoides*, and *Ziziphus nummularia*. Summer rains aid in the growth of lush grasses and herbs from seeds that lie dormant in the winter soil. This summer bloom helps sustain wildlife and livestock populations.

Knuckles Mountain Range, Sri Lanka

The geography of Sri Lanka can be described as three massifs, running north to south. The Knuckles mountain range forms the northernly massif. This range forms the northern block of what is known as “Hill country” but is isolated by the Kandy plateau and the broad Dumbara valley, both to the south of the range. The range got its name from a series of stretched folds and peaks in the west which resemble the knuckles of a clenched fist.

The pattern of rainfall varies widely across the Knuckles mountains. It receives rainfall from both the southwest and northeast monsoons. The highlands and the western areas of the range are wet throughout the year and experience an annual rainfall of about 5000 mm, whereas the lower eastern slopes are not as wet, receiving an annual rainfall of 2500 mm. The area's mean annual temperature outside the massif is more than 26 °C, and this value falls to about 21 °C at elevations above 915 m and to about 18.5 °C at the highest elevations.

River and Drainage

The Knuckle Mountain Forest Range (KMFR) plays an important role as a watershed, housing more than 500 streams that is an origin point for many rivers and streams that drain East into the lower Mahaweli River system (Heen Ganga, Hasalaka Oya, and Maha Oya), southwest into the upper Mahaweli River system (Hulu Ganga), and northeast into the Amban Ganga River system (Kalu Ganga, and Teligam Oya). The KMFR catchments area contributes about 30% of water to the three reservoirs (Victoria, Rantamgala and Rantambe) of the Mahaweli River system.

Biodiversity

Typical patches of sub-montane forest are found at Cobert's Gap in Kelabokka. The Riverstone area and the trees in the sub-montane forest are stunted, much branched and aerodynamically shaped by strong winds. Approximately 1033 species of vascular plants are found, including 170 endemic species of woody trees (3% of which are nationally threatened) and several endemic flowering herbs. Also, it harbors 33% of all the flowering plant species of the island. Around 262 species of vertebrates have been recorded, of which around 69 are endemic and 60 are nationally endangered. There are several species of fish, amphibians and reptiles that are endemic to the Knuckles range. Out of 21 endemic species of birds of Sri Lanka, 14 are endemic to this specific region. Among the fauna, 5 species of amphibians, 6 species of mammals and 10 species of reptiles are threatened. The Knuckles range is inhabited by various mammals such as wild boar, spotted deer, giant squirrel, barking deer, purple faced leaf monkey, mongoose and porcupine. The endemic lizard species found at Knuckles range include the Crestless Lizard (*Calotes Leiocephalus*), Pigmy Lizard (*Cophotis ceylonica*), Kangaroo Lizard (*Otocryptus Wiegmanni*) and leaf nose lizard (*Ceratotheca Tennentii*).

Pamir Mountain Range, Afghanistan

The Pamir region, also known as the Gorno-Badakhshan, lies on an elevated plateau in the center of the mountainous Badakhshan region, in north-eastern Afghanistan and south-eastern Tajikistan. Although the exact extent of the Pamir range is debatable, most of it falls within the borders of Tajikistan, with some fringes extending into Afghanistan, China and Kyrgyzstan.

The eastern Pamirs rise from a high-elevation foundation, with the average elevation being a minimum of 6100 m. The climate of the Pamirs is typical of cold desert and semi-desert, characterized by extreme winters and warm, dry summers. The mean temperature during the former season ranges between 2 and 10 °C, while the annual average trends between 0 to –8 °C. Summer storms are a common feature in western valleys. Most wind activity and movement patterns are influenced by the Afghan winds from north-western Afghanistan. These winds intensify over ridges in the lower Pamirs, resulting in dust storms and frequent rainfall. The frigid winters limits growth of forests, with the climate made more hostile to trees by the presence of strong dry winds.

Rivers and Drainage

The primary drainages of the northern Hindu Kush-south western Pamir area originate within the Harirud fault, in a sharp and irregular drainage that divides them and the southern rivers of central Afghanistan. The rivers drain an arid region and join the Amu river. The rivers exhibit sharp knickpoints (a point in a river or channel where there is a sharp change in channel slope), cutting the main Hindu Kush range, while traversing the intramontane faults. The rivers draining southwestern Pamir show much higher gradients and flow north. These rivers are incised throughout their courses, except in their upper reaches where they flow on Quaternary glacial outwash.

The main Pamir mountains are drained predominantly by Pyandzh–Amu river and its tributaries. The river exhibits a gentle profile and show several incisions throughout its course, except on the central plateau and the lower Amu reaches. This is the only drainage for the main mountain system without much disruption. The right bank, however, houses many more tributaries and is responsible for draining most of the northern and central parts, flowing over major thrust lines. The rivers of the north Pamir mountains flow in a westward direction into the Kyzylsu and Vakhsh tributaries to the Amu. The primary river of the Trans- Alai

valley, the Kyzylsu–Surkhab–Vakhsh, exhibits a disruption in its middle and lower reaches and runs along the compression zone between North Pamir and Tien Shan.

Biodiversity

The Pamir shares a distinct ecological similarity with the Mediterranean type gravelly desert at lower elevations. With gradual elevational ascent, the community changes to thorny cushion plants, supported in an open steppe habitat. Further uphill, the higher steppe community supports abundant growth of needle grass and fescue grass. The higher elevations harbor alpine meadows. The upper limit of vegetation is typified by hardy perennial flora. The alpine flora of the Pamir shows high phytogeographical similarities to the Tibetan plateau.

The drier eastern Pamir harbors several avian species such as the brown-headed gull (*Larus brunnicephalus*), bar-headed goose (*Anser indicus*), two species of snow cock (*Tetraogallus himalayensis* and *T. tibetanus*). The Pamirs also are home to an array of mammals; some of the endangered encountered mammals include the brown bear (*Ursus arctos isabellinus*) and snow leopard (*Uncia uncia*). Several species of goat and wild sheep are also commonly encountered across the desert and tundra region, the most abundant being the Siberian Ibex (*Capra ibex sibirica*) and the Marco polo sheep (*Ovis ammon polii*).

The Salt Range, Pakistan

Salt Range is a series of hills and low mountains between the valleys of the Indus and Jhelum rivers, located in the northern part of the Punjab region of Pakistan. It derives its name from extensive deposits of rock salt that form one of the richest salt fields in the world. The range is approximately 300 km long from east to west, and its width ranges from 8 to 25 km. Its average height is 660 m and its highest altitude, at Sakesar mountain, is 1522 m.

The climate of the Salt Range is continental and arid, ranging from tropic to subtropic. Tropical air prevails during all seasons of the year except the cold winter months, when relatively cool polar air penetrates at the tail end of high-pressure systems (cyclones). During summer, precipitation is linked with the equatorial, moist, southwestern (Indian) monsoon, which reaches the limits of its occurrence in West Punjab but brings the largest amounts of precipitation (more than 50% annually).

Rivers and Drainage

To the west of the Indus river, the Jhelum runs south into the districts of Bannu and Dera Ismail Khan. It sinks gently towards the Potwar Plateau in the north. The salt range is divided into two parts:

1. Main Salt Range or Cis-Indus Salt range, lies east of river Indus
2. Trans-Indus Salt Range, lies to the west of river Indus

Part of the Central Salt Range has a wetland called “Uchhali Wetlands Complex” located in the Khushab District. It encompasses three lakes: the Uchhali Lake, the Khabbeki Lake and the Jahlar Lake. These lakes are mainly fed by local rainfall, small springs, seepage from adjacent irrigated land and run off from surrounding hills.

Biodiversity

The Salt Range is bestowed with a great diversity of habitats and has a correspondingly rich species diversity. Dominant trees are *Acacia modesta*, *Olea ferruginea*, *Tecomella undulata* and *Butea frondosa*, whereas dominant shrubs are *Dodonaea viscosa*, *Justicia adhatoda*, *Maytenus royleanus*, *Ziziphus nummularia* and *Buxus papillosa*. Over 60 palatable grass species have been recorded from the area, dominant among them are *Chrysopogon serrulatus*, *Heteropogon contortus*, *Dichanthium foveolatum*, *Cynodon dactylon*, and *Aristida mutabilis*.

A total of 138 bird species have been recorded, belonging to 13 orders and 48 families. Most of the birds are migratory and few are resident. The rose ringed parakeet, house crow, house sparrow, mynas, and bulbuls are common among the resident birds, while kingfisher, koel, rollers, and tree pie are increasingly rare. The Grey Francolin is widely associated with the drier regions of the Indus plains and has penetrated the salt range and agroforestry tracks of the Pothwar Plateau in the Punjab. Quail and Grey Partridge are found in large numbers as there are many places providing shelter for their breeding and other activities. The Red Turtle Dove is a summer visitor and the spotted dove is common. Rock Pigeon, Hill Pigeon, Snow Pigeon, Pale-backed Pigeon, Common Wood-Pigeon, Speckled Wood-Pigeon, Eurasian Turtle Dove, and other members of the same family are migratory summer visitors.

Sulaiman Mountains, Afghanistan and Pakistan

The Sulaiman mountains are a folded mountain belt which was formed by the collision of Indo-Pakistan and Eurasian plates. The range derives its name from the name of Prophet Solomon, who is said to have climbed this mountain. The Sulaiman range runs north in Loya Paktia and meets the Spin Ghar range northeast of Gardez in Paktia province. To the northwest, the Sulaimans merge

beyond Loya Paktia into the Koh-i-Baba range. To the east, the Sulaimans enter the districts of Dera Ghazi Khan in Punjab and Dera Ismail Khan in Khyber Pakhtunkhwa, and approaches the Indus River near Mithankot in the Rajanpur District of Punjab. The eastern slopes drop very quickly to the Indus River, but the mountain range drops gradually towards the west, in Kandahar southwest into Helmand and the Sistan Basin.

The climate of the area varies in terms of precipitation and temperature. Summer temperatures are hot (up to 35° C) while winters are cold, with temperature as low as -15° C. Also, there is a strong diurnal variation in temperature. Rainfall is mostly light (270–300 mm/year) and occurs in summers. Winter precipitation mostly falls as snow. The region lies on the path of passing western disturbances carrying moisture laden winds from the Mediterranean Sea. These winds provide moisture in winter.

River and Drainage

Two major rivers originate from the Sulaiman mountains. The Gomul river, which flows towards east into the Indus river, and the Dori river and various other small tributaries of the Arghandab river which flow south westward into the Helmand river.

Biodiversity

The Suleiman Range has the world's largest pure stand of Chilgoza forests and is home to the endangered Suleiman Markhor. It includes the Niazi Kot, Ghundai Kun, Lakai, Kachai and Ahmadi Dargah valley district. Two distinct forest types exist in the area: dry temperate forest and sub-tropical broad-leaved evergreen forest. The flora includes *Pinus gerardiana* (Chilgoza), *Pinus wallichiana* (Kail or Nashtar), *Olea ferruginea* (Showan), *Pistachio cabulica* (Ozgai), *Pistachio khinjuk* (Sharawan), *Prunus eburnea* (Wild Almond), *Perowskia abrotanoides* (Shinshab), *Salsola foetida* (Lani), *Daphne* spp. (Laghunrd), *Acacia modesta* (Phulai), *Artemisia maritime* (Jhau), *Ziziphus nummularia* (Karkanda), *Fraxinus zanthoxyloides* (Shang) and *Monothea buxifolia* (Gurgura).

Mammals found in the region include the Suleiman Markhor, Common leopard, Black bear, Fox, Wolf, Asiatic Steppe Cat, Hyena, Asiatic Jackals, Indian Crested Porcupine. Many snake species have also been reported from the area. The braid snake, *Platyceps* (formerly *Coluber*) *rhododracus* and *Agama* lizards. are common. Birds found in the region are the Eurasian Griffon Vulture, long legged buzzard, partridge, Chukor, Blue rock pigeon, Oriental turtle dove, Little swift, Kashmir roller, Greater shirt toed lark, crested lark, small skylark, Long billed pipit, Water pipit, Grey Headed yellow wagtail, rufous backed redstart, collared Indian bushchat, pied bushchat, Isabelline wheater, Eastern pied wheater, Indian robin, Blue rock thrush, Black throated thrush, Blyths reed warbler, Great tit, Himalayan tree creeper, Jungle crow, and Migratory house sparrow.

Toba Kakkar Range, Afghanistan and Pakistan

The Toba Kakkar range in the Zhob and Quetta-Pishin districts of Baluchistan forms the transboundary between Baluchistan and Afghanistan and the watershed between India and Central Asia. It descends towards the west and opposite Chaman, taking a sharp turn to the south west, continuing under the name of the Khwaja Amran and Sarlath. The Torghar Mountains experience dry cold winters (average mean temperature 4 °C) and warm summers (average mean temperature 26 °C). The area receives heavy snowfalls in winter and violent thunderstorms in summer. Total annual precipitation lies between 180 mm and 270 mm, making the region semi-desert.

Biodiversity

The Torghar hill of Toba Kakkar range is a semi desert landscape dominated by shrub steppe plant communities. In upland slopes, the vegetation that flourishes includes Bunchgrasses, forbs, wild almond (*Amygdalus brahmica*) trees, *Ephedra* sp., *Artemisia* sp., and other shrubs. However, in low lying area, plants such as *Cargana* sp. and *Tamarix* sp. grow at places where water is available. Trees are rare, but include juniper (*Juniperus macropoda*), wild pistachio trees (*Pistacia khinjuk*), and almond trees are scattered across the landscape. The mountains of northern Balochistan were rich biodiversity as recently as the 1950s, and had significant populations of Suleiman markhor, Afghan urial, leopards, Asiatic black bears (*Ursus thibetanus*), etc. Unchecked hunting led to regional extirpation of the leopard and black bear in the Torghar hills in the mid-1980s. By then, the total combined regional populations of markhor and urial were estimated at about 200 head. Today only small populations of the following species are found here: Suleiman markhor, Afghan urial, wolf, hyaena, fox, Pallas's cat, steppe wild cat and stone marten.

The Western Ghats, India

The Western Ghats (also known as the *Sahayadris*—"benevolent mountain") are a chain of continuous mountains that run along the west coast of peninsular India from Tamil Nadu through Kerala, Karnataka and Goa to Maharashtra. Older than the Himalaya mountains, the mountain chain of the Western Ghats represents geomorphic features of immense importance with unique biophysical and ecological processes. The site's high montane forest ecosystems influence the Indian monsoon weather pattern. Moderating the tropical climate of the region, the site presents one of the best examples of the monsoon system on the planet. It also has an

Table 3 Classification of the Eastern Ghats.

<i>Group</i>	<i>Reserve (Sub-region)</i>	<i>State</i>
Agasthyamalai Group	Kalakad-Mundanthurai Tiger Res.	Tamil Nadu
	Shendurney Wildlife Sanctuary	Kerala
	Neyyar Wildlife Sanctuary	Kerala
	Peppara Wildlife Sanctuary	Kerala

Sahyadri Group	Koyna Wildlife Sanctuary	Maharashtra
	Chandoli National Park	Maharashtra
	Radhanagari Wildlife Sanctuary	Maharashtra

exceptionally high level of biological diversity and endemism and is recognized as one of the world's eight "hottest hotspots" of biological diversity. The Western Ghats cover approximately 795,315 ha and are divided into seven separate groups containing 39 reserves spread over 1250 km, listed below from south to north (**Table 3**).

The coast and lower foothills are humid and tropical; elevations above 1500 m in the north and the higher regions of the south are more temperate. The west side of the mountains intercepts the prevailing southwesterly monsoon winds between June and September when 65–80% of the rain falls. Most of the rest falls during the northeast monsoon between October and November. The rainfall on the west side averages 2000–3000 mm with local extremes up to 10,000 mm. The eastern slopes in the rain shadow receive an average of about 1000 mm near the crest. Average annual temperatures range from around 15 °C in the north to 35 °C in the south. At some high elevations temperatures touch 0 °C during the winter and frost is common.

Rivers and Drainage

A total of 81 rivers originate in the Western Ghats. There are two types of rivers: west flowing and east flowing. The water of west flowing rivers is discharged into the Arabian sea at a faster flow rate due to shorter distance and steeper landscapes. The rivers flowing eastwards are generally slow and merge with large rivers such as the Kaveri and Krishna. The west flowing rivers of the Western Ghats are the Periyar, Bharathappuzha, Netravati, Sharavathi, and Mandovi. Rivers that flow towards the east are the Godavari, Krishna and Kaveri.

Biodiversity

Agasthyamalai Group: Shendurney Wildlife Sanctuary has 951 vascular plant species, 309 being endemic to the Ghats, and 100 endangered species. Neyyar Wildlife Sanctuary has several threatened trees and 125 orchid species. The Kalakad-Mundanthurai Tiger Reserve shelters 43 mammals, 245 birds, 43 amphibians, 46 reptiles and 42 fish. Found in the sites of the group are the Asian elephant, tiger and gaur. There are also large populations of the endemic lion-tailed macaque (*Nilgiri langur*), the Nilgiri marten, the sloth bear and the Nilgiri tahr (Radhakrishnan and Rajmohana, 2012).

Periyar Group: 75% of the site is covered by tropical wet evergreen forest, 13% by moist deciduous forest. Eight vegetation types are present with 1651 vascular plant species—50% of Kerala's total. There are 77 species of Cyperaceae, 10 species of palm and 145 orchids. In the Periyar Tiger Reserve and adjoining sites 62 mammals, 330 birds, 27 amphibians, 45 reptiles, 38 fish and 160 butterflies are recorded, almost the highest overall count in the property.

Anamalai Group: There are six vegetation types and 297 grassland and 108 fungi species. Karian Shola is a separate, very small, mid-level rain forest park at 650–1000 m. In Eravikulam and Grass Hills National Parks there are 29 mammals, 132 birds, 20 amphibians and 101 species of butterflies. In addition to the flagship and local large mammals there are the Nilgiri marten and dusky palm squirrel (*Funambulus sublinea*). One thousand five hundred of the Western Ghats' population of over 2000 Nilgiri tahr (EN) are found here.

Nilgiri Group: This is one of the most important landscapes with a 6000 km² tropical evergreen forest in the southwest and dry euphorbia scrub in the southeast. There are five vegetation types dominated by tropical wet evergreen forest in the west and shola grassland in the hills; with 966 vascular plants, and 108 orchids. Alpine type flora includes the 12-yearly flowering blue flower after which the Nilgiris, the blue mountains, are named.

Talacauvery Group: The vegetation here is predominantly west coast dense tropical evergreen and semi-evergreen forest with shola grassland at high elevations. Seventy tree species are endemic to the Western Ghats. Brahmagiri Wildlife Sanctuary has undulating terrain with steep valleys and is similar in character with thickets of bamboo growing in formerly farmed areas.

Kudremukh Group: Kudremukh National Park has a large continuous forest of tropical evergreen forest below 300 m with deciduous forest and a wide expanse of grassland above 1000 m. Eighty-eight species are endemic to the Maharashtra Ghats. The number of animal species is very high: 33 mammals, 181 birds, 36 amphibians, 54 reptiles, 23 fish, 73 molluscs and 149 butterfly species are recorded.

Sahyadri Group: The Kas Forest region is called the plateau of flowers: it has 850 plant species including many ephemeral herbs and bulbs. Radhanagari Wildlife Sanctuary is the habitat of a large range of animals: 47 mammals, 264 birds, 20 amphibians, 59 reptiles, and 66 butterflies.

Summary

South Asia extends south from the main part of the continent to the *Indian Ocean*. The principal boundaries of South Asia are the Indian Ocean, the *Himalayas*, and Afghanistan. The *Arabian Sea* borders Pakistan and India to the west, and the *Bay of Bengal* borders India and Bangladesh to the east. The western boundary is the desert region where Pakistan shares a border with Iran. The majority of the South Asian landmass was formed from the land in the original Indian Plate. This action started about 70 million years ago and gave rise to the highest mountain ranges in the world.

The balancing of natural landscapes with human population growth is and will remain a primary issue in the realm's future. South Asia is highly populated, with about one-and-a-half billion people (Ebi et al., 2007).

The mountain ranges of South Asia form the backbone of their respective countries. They play a pivotal role, in providing natural resources. A large fraction of the human population depends directly or indirectly on these natural resources. Fresh water sources that originate from these mountains are unparalleled in terms of the population sizes they support.

Abstract

Today, some still consider the higher elevations of the European Alps as mostly wild or “natural” landscapes; biomes that have to some extent avoided the consequences of human economic activities. This article explains how this notion is misplaced via an overview of the interplay of climate, topography and human activity. Offering a synthesis of recent research from across the alpine arc, this contribution considers how human-environment interactions have developed through the Holocene. The evidence employed here focusses on palaeoenvironmental archaeological evidence spanning the Alps, from Austria to France.

Introduction

The history of human exploitation of alpine regions is undeniably complex, but more importantly, it is a history that reveals the ability of people to exploit one of the most ecologically and geomorphologically, complex, demanding and unpredictable regions on the planet’s surface. In the 21st century, some still consider the high elevations of the Alps to be “natural” landscapes; these areas are the product of human activities that span the entire Holocene. Despite the difficulty of living and working in the mountains, these landscapes offer a wide variety of niches, and other resources, including minerals. Certain regions of the Alps have been critical nodal economic points in complex networks, linking the Alps to other regions across the wider continent. Here, we present a chronological overview of the important phases and trends of human-environment interactions in the Alps spanning the Holocene (see **Table 1** for a breakdown of archaeological periods and their dates). Geographically, we define the European Alps as stretching from the French Alps in the west to the Slovenian Alps in the east; running via the Swiss, Italian and Austrian Alps (**Fig. 1**).

Alpine Biomes—Regional Variation

The Alps are situated between two other significant biomes with concomitant climatic and ecological influences: zones with temperate broadleaf deciduous forest to the north and the Mediterranean biome to the south (**Quinn, 2008, p. 122**). Also, the spatial extent of the Köppen-Geiger climate zones has fluctuated with time, with the external alpine areas moving in and out of

Table 1 Archaeological chronological periods.

Age	Cultural period
After 568 AD	Middle Ages
375–568 AD	Migration Period
15 BC–375 AD	Roman Period
450–15 BC	Late Iron Age
800–450 BC	Early Iron Age
1350–800 BC	Late Bronze Age
1550–1350 BC	Middle Bronze Age
2200–1550 BC	Early Bronze Age
3700–2200 BC	Chalcolithic
5500–3700 BC	Neolithic
6500–5600 BC	Late Mesolithic
10,000–6500 BC	Early Mesolithic

N.B. There is some variation across the region; this table is a broad framework.

the boreal and alpine climatic classification. The southern Alps in France and Italy are influenced by the Mediterranean climate especially with regards to hydrological activity (Wilhelm et al., 2012; Wilhelm et al., 2017). The natural timber and tree lines are higher here than other parts of the Alps. In the northern Swiss Alps, the potential timberline is 2000–2200 m, whereas the actual timberline is 1700–1900 m (Röpke et al., 2011). The maximum treeline in the central European Alps should be around 2500 m (Carnelli et al., 2004), while in the southern French Alps, charcoal studies suggest that the treeline was as high as 2700 m until about 5000 years ago (Talon, 2010). Further east, in the Austrian Alps, tree-ring series from subfossil logs also reveal that the timberline reached its highest level (> 2400 m asl.) during the Holocene Climatic Optimum, i.e., between 4000 and 2500 BC (Nicolussi et al., 2005). These regional variations have consequences for biome trajectories and how certain human activities have developed during the Holocene.

The spatial extent of glaciers influences the elevation of ecotone boundaries and ecological reproduction rates (pedogenesis and vegetation growth) in front of the glacier. The extension of permafrost zones, and then areas with shorter growing seasons, limited any activity that comprised the exploitation of vegetation, especially grazing. Glacier extent also influenced how people moved, lived and worked in and around alpine areas. Areas, such as the Schnidejoch, Lötschenpass, Tisenjoch, and Gemsbichl/Rieserferner glaciers were traversed during the Neolithic and Bronze Age, with archaeological materials now exposed as the ice retreats (Hafner, 2012).

Definition of vertical ecological zones

It is rare for any permanent settlement to exist above 2000 m. In the Alps, the highest parish or communes are Trepalle (Italy) at 2209 m, Juf (Switzerland) at 2126 m and Saint V  ran (France) at 2040 m. This contribution focusses on the development of human-environment interactions in the higher elevation zones, taken here as the zones above 1000 m. In turn, for each chronological period discussed below, we focus on the palaeoenvironmental and archaeological evidence for the montane zone (c. 500 m in the northern Alps and 1000 m in the southern Alps), and the sub-alpine and alpine zones (starting c. 1200 m in the northern Alps and 1700 m in the southern Alps) (Fig. 2). This upper limit of the sub-alpine and into the alpine zone is notionally the area that is only exploitable during the summer months, although there are certain activities, such as mining, that take place outside of the clement period. Today, the limit of forest/woodland (the treeline), tends to be situated at the start of the sub-alpine zone, with the alpine belt comprising shrubby and grassy vegetation. From an archaeological/anthropogenic perspective, these zones are important as they influence the development of some important activities, for example, hunting and pastoralism in the sub-alpine zones appear to have been concentrated in the areas between 1500 and 2300 m, zones where the forest, especially towards 2000 m, would have been more open and facilitated hunting and pastoral activities.

Defining mountain landscapes

The defining characteristic of mountainous areas is vertical zonation; the relationship between environments (climate, vegetation, soil) across the vertical zones, the types of activity that can take place therein and when (in which season) these activities can take place. These notions underpin the framework and models for much research in mountains. The reduction in temperature of 0.6  C for every 300 m climbed is a defining environmental variable in mountainous areas. Biogeographical models have influenced how we interrogate and interpret human-environment engagements in the Alps. The application of such models when assessing human colonization and life in high altitude zones is problematic. There are, however, simple, unavoidable biogeographical rules: at a general level, pedogenesis decreases with elevation, although there are variations dependent on microtopography, hydrology and local temperature variances (Poulenard and Podwojewski, 2006). Unsurprisingly, the number of different species of plants and animals also decreases. While the primary productivity of an alpine zone influences forms of hunting, gathering, farming, and pastoralism, with most of these activities typically taking place during the summer months, there are specific resources, especially minerals and ores that can be exploited all year round (Fig. 3).

Fig. 2 The altitudinal zones across the European Alps. This contribution focusses on human-environment interactions across the montane and sub-alpine zones. Based on Pethrus (https://commons.wikimedia.org/wiki/File:Altitudinal_zones_of_Alps_mountains_Extended_diagram-fr.svg), text by K.J Walsh, <https://creativecommons.org/licenses/by-sa/4.0/legalcode>.

Fig. 3 The relationship between altitudinal zones and seasonal human activities is fundamental. For example, Mesolithic hunting and gathering would have taken place during the summer months. High-altitude grazing, as represented in the right-hand section of this figure, also takes place during the summer months. Detail of typical altitudinal zones with concomitant vegetation bands. The Holocene climate, environment and landscape

As with most regions, the Alps warmed rapidly from the start of the Holocene, as inferred from several proxies. Proxies from lake sediments in the Swiss and Austrian Alps, including beetle, cladoceran, chironomid, pollen and isotopic signatures of biogenic carbonates, reveal a rise of about 2.5–4°C during the transition to the Holocene (~9700 BC). There are variations in these records that are dependent on altitude (von Grafenstein et al., 1999; Lemdahl, 2000; Heiri and Lotter, 2003; Lotter et al., 2006). Beetle evidence from the Swiss Alps that suggests rapid warming at the end of the Younger Dryas and the start of the Pre-Boreal (von Grafenstein et al., 1999; Lemdahl, 2000; Heiri and Lotter, 2003) (Fig. 4). The increase in temperature during the transition to the Holocene resulted in significant changes in the altitudinal displacements of trees and other plants (ecotone movement) (Berthel et al., 2012). One of the most important corollaries of climate warming in the Alps was glacier contraction; fundamentally important as the newly exposed land surfaces were colonized by plants and animals, creating new niches potentially exploitable by hunter-gatherers (Le Roy et al., 2017). Treeline advance plays a fundamental role in the development of niches for all mammals; the treeline forms an ecotonal boundary, a zone where animals (including people) have access to different floral communities. In the central Swiss Alps, glacier retreat took place during the Mesolithic (8000–6000 BC) (Hormes et al., 2001). Similar phases of glacier retraction have also been identified in the Bernina Massif in the Swiss Alps (Joerin et al., 2006).

Mesolithic Activity

People moved into the high-elevation zones for hunting at the start of the Early Holocene. In the Venetian Pre-Alps, evidence derived from a palynological core from the Palughetto basin at c. 1000 m and archaeological sites between 1900 m and 2400 m demonstrate the presence of late Early Mesolithic peoples, hunting in forests (Avigliano et al., 2000). The development of bows and arrows may be an adaptation to forest hunting where medium-sized prey was targeted during the early Holocene (Tomka, 2013). Lithic artifacts in Trentino span the transition to the Holocene; deer were often hunted in this area, both for food and as a source of workable bone for tools (Bazzanella, 2001, 2005). Many of the Mesolithic (c. 6500 BC) sites were located at high elevation (between 1800 and 2300 m), with lower sites at c. 1000 m interpreted as intermediate camps on routes between valley bottoms and the high-elevation hunting grounds. In the western Swiss pre-Alps, rock shelters from 900 to 1200 m were occupied c. 9500 BC, while open-air sites are between 1400 and 1700 m (Crotti and Bullinger, 2008). Climatic amelioration brought denser forests, forcing hunters to become more mobile and to hunt in clearings. Mesolithic hunting sites above 2000 m show a preference for open ground where prey could be more easily spotted and killed.

It is difficult to demonstrate any significant impact of hunter-gatherers on alpine environments, although they may have cleared small areas of forest to attract prey, a process identified in some parts of Europe, including North Yorkshire (Simmons and Innes, 1996). Farming began in the Neolithic in the Alps, initiating human impacts on alpine environments.

Neolithic

Across the Alps, the valley bottoms were colonized and landscapes modified by early farmers. Pollen records and some sedimentary archives reflect the creation of new cultural niches (Smith, 2011). Forest was cleared, and arable land was developed. Farming gradually moved upslope to mid-high-elevation areas (Walsh et al., 2014). There was little human impact on the sub-alpine and alpine

Fig. 4 Holocene climatic trends in the Alps. Oxygen isotopes on ostracod shells (A) from Lake Ammersee sediments can be used as proxy for mid-European (at the northern alpine front) past temperature (von Grafenstein et al., 1999). Oxygen isotopes from Spannagel speleothems (B) is a climatic proxy for Eastern Alps (Fohlmeister et al., 2013). The abrupt shift recorded from 6000 years ago may reflect higher precipitation. Chironomid community composition from Lake Egelsee in Central Northern Alps (C) is used to reconstruct past summer (July) temperature (Larocque-Tobler et al., 2010). The Treeline evolution in Austria (D), obtained from dendrochronological analyses from living trees and subfossil logs (Nicolussi et al., 2005), reflects a mix between climatic changes and anthropogenic activities (deforestation). Glacier fluctuations in Switzerland and Austria from dendrochronological and ^{14}C analyses ((E) Holzhauser et al., 2005, 2005; (F) Nicolussi and Patzelt, 2001; Joerin et al., 2006, Joerin et al., 2008; Kellerer-Pirklbauer et al., 2008; Nicolussi and Schluchter, 2012) (all figures redrawn by Giguët-Covex).

zones in the Neolithic, but people were moving into, and through these areas; Neolithic artifacts from the melting ice on the Schnidejoch Pass (2756 m) in Switzerland demonstrate human traffic across high alpine passes (Hafner and Schwörer, 2018).

Neolithic alpine valley farming focussed on wheat and barley with certain varieties of spring wheat growing as high as 2000 m in some areas of the Swiss Alps (Martin et al., 2008). However, there was little farming in the sub-alpine zone, and hunting and gathering remained important here (Binder and Centre de recherches archéologiques, 1991). At 1720 m in the French Alps, people gathered plants from their campsite, up to subalpine areas 400 m higher (Martin et al., 2012). In parts of the Swiss Alps, farming settlements were created during the sixth millennium BC (Della Casa et al., 2013; Jacquat and Della Casa, 2018). There is little evidence for human impact at high elevation at that time. However, the planting of nitrogen-loving agricultural crop species changed the soil chemistry of farmland.

Early human impact on the (sub)alpine zone and the development of pastoralism—The transition from the Neolithic to the Chalcolithic

First, we should explain the idiosyncrasies of archaeological chrono-typologies: the division of the past into periods founded on fundamental cultural and technological changes. The Chalcolithic is in some ways a hybrid period, one characterized by the continued use of Neolithic technologies (specific lithic tools and agricultural systems) and the start of copper extraction and working. This period broadly starts at c. 3500 BC. This period is of fundamental importance in the Alps as the development of mining and the intensification of pastoralism, have significant consequences for our landscapes.

An example of early high-elevation activity comes from the Italian central Alps. Here, archaeological and palaeoecological evidence demonstrates Neolithic activity at elevations between 1800 and 2300 m. The upper limit of this activity was probably at the upper limit of vegetation. The presence of Early Neolithic charcoal at the timberline in this region indicates human impact on the forest (Wick,

1994). Palaeoecological evidence from a lake at 2065 m near Schnidejoch suggests high altitude pastoralism by c. 4700 BC (Schwörer et al., 2014). In the Silvretta Alps, there is evidence for Middle Neolithic farming, although cereal pollen from c. 4200 BC and 3400 BC likely came from lower elevation farms. There is evidence for Neolithic occupation at high-altitude, from a shelter dated to c. 4300 BC. This corresponds with the contemporaneous presence of cereal pollen at 2170 m in the Lower Engadine. By c. 3600 BC open *Larix* meadows indicate pasture at 1590 m near Ardez. Pastoralism was significant in these areas by 2200 BC (Della-Casa et al., 2013; Dietre et al., 2014; Kothieringer et al., 2015). Moving west, to the northern French Alps, the first pastoral activities, as high as 2000 m, are tentatively dated to around 2900 BC. The clearance of *Pinus cembra* suggests the development of such activity, an increase in erosion, and the first record of cow DNA in sediments from Lake Anterne also support the suggestion that pastoral activity developed at this time (Giguet-Covex et al., 2014; Pansu et al., 2015). However, the lowering of the treeline and the increase in erosion might also be explained by the transition towards the Neoglacial Period, i.e., a colder and wetter period (Wanner et al., 2008). Still in the northern French Alps, but at lower elevation, Late Neolithic cow DNA has been identified in sediments sampled from Lake La Thuile (900 m asl, in the Massif des Bauges). Interestingly, this pastoral activity developed in a forested area as demonstrated by the presence of DNA from fir and alder (Bajard et al., 2017a,b; Giguet-Covex et al., 2019; Fig. 12).

Pollen evidence from the southern French Alps reveals human activity across the full range of elevations (Court-Picon, 2007; Walsh et al., 2014). It is apparent that Neolithic populations were farming the valley-bottoms, and that human impact on the high-elevation (sub-alpine and alpine zones) landscapes did not develop until the end of the Neolithic and Chalcolithic (Walsh and Mocci 2011).

Chalcolithic to Bronze Age

Pastoralism, lactase persistence and niche creation

At c. 2200 BC, the transition between the Middle and Late Holocene (Walker et al., 2012), we move into a phase of complex climatic oscillations that would have influenced the ecological characteristics of alpine biomes. This period comprised a “mélange” of climatic and societal changes (Roberts et al., 2011). During the Chalcolithic and Bronze Age (from c. 3000 to 1000 BC), alpine landscapes, especially the sub-alpine altitudinal belt, emerged as the product of a complex set of co-evolutionary processes. The increased exploitation of secondary products (milk-products, wool, traction) (Sherratt, 1981; Greenfield, 2010) intersected with the increase in lactase persistence in many humans across Europe (Shishlina, 2005; Leonardi et al., 2012). Lactase persistence is strongly correlated with pastoralism (Holden and Mace, 1997, 2002), although it seems likely that pastoralism was adopted before people developed the ability to digest milk (Leonardi et al., 2012). The intensification and extension of pastoralism that included high-altitude summering in the Alps was part of a process where a form of agriculture and landscape management was inextricably linked with the extension of the lactase persistence gene via increased consumption of dairy products (Gerbault et al., 2011).

From the late third to mid-second millennium BC palaeoenvironmental and archaeological evidence reveal a significant extension and intensification of human activity in the higher zones of the Alps. In the Austrian Central Alps, pastoral activity developed by 3000 BC (Schmidt et al., 2006, p. 502). In the Swiss central Alpine region at 1210 m, cattle farming increased throughout the Bronze Age, at the expense of sheep and goats (Bopp-Ito, 2012). Pasture creation per se is not required for sheep/goats as these animals can seek out food for themselves. However, cattle require better quality grass, so pasture creation and increasing cattle herds went hand in hand. Dairy farming and the use of cattle for traction became more important (Bopp-Ito, 2012).

Pollen evidence from the Central Austrian Alps records pastoral activity from the mid-second millennium onwards (mid-late Bronze Age) (Schmidt et al., 2002) and in the St Antönien Valley (Switzerland) at 1400–3000 m) from c. 1300 BC. A study from 2343 m in the Central Swiss Alps suggests forest opening from about 2700 BC (Tinner et al., 1996). In the Ötztal Alps, evidence for human impact at high elevations dates to the Middle Bronze Age. In the southern French Alps, the first stone-structures associated with pastoralism date to c. 2500 BC are found at elevations between 2100 and 2400 m (Fig. 5) (Walsh et al., 2005). Palynological evidence for the third and second millennia BC indicates an intensification of pastoral activities (Court-Picon et al., 2007; Mocci et al., 2009; Richer, 2009). On certain high elevation sites, fungal spores and nitrophilous plant pollen indicate Bronze Age pastoral activity in the immediate vicinities of these sites (Walsh et al., 2006) (Fig. 6). Moreover, charcoal evidence from the pollen cores, along with charcoal from sediments found within and around the archaeological sites, is indicative of woodland clearance designed to create more suitable pasture.

Mining as a driver of landscape change

Unsurprisingly, the activity that characterizes this period (the Bronze Age) is the development of copper mining. Miners would have used wood and timber in a variety of practices, including fire-setting for the extraction of copper ore (Bourgarit et al., 2008; Barge and Talon, 2012a,b). At a fen near Falkenstein (Schwaz, Tyrol, Austria), the lead scandium ratio increased during the Neolithic to Bronze Age transition; this combined with the increase in charcoal values from the Middle Bronze Age suggest increasing impact on this environment over time (Breitenlechner et al., 2010).

The intensification of agricultural activities in the Alps was often linked with the increase in mining activity. Miners required food, and new “wealth-producing” activities would have attracted people to the mineral and ore-bearing areas of the Alps. In the Montafon Valley in the Voralberg area of western Austria, human activities combining mining and farming are apparent from c. 3000 BC onwards. During the Early-Middle Bronze Age, people gradually extended their use of the landscape at higher altitudes. Non-arboreal pollen values for this period are equivalent to those of today. Crops exploited in the area included barley and emmer wheat (*Hordeum vulgare*, *Triticum dicoccum*) and spelt (*Triticum spelta*), with rare examples of Broomcorn millet (*Panicum*

miliaceum) (Schmidl et al., 2005). In the Salzburg area, mining and pastoral activities contributed to changes in the landscape and an opening up of the forest (Breitenlechner et al., 2010, 2014). In the French Alps, high levels of copper in lake sediments from the Grandes Rousses Massif (c. 2400 m) reveal the impact of mining activities in the area (Guyard et al., 2007). Evidence for fire setting dated to 1750–1520 BC comes from the copper mine at Saint Véran and is dated to 1750–1520 BC (Fig. 7). *Pinus cembra* was the predominant choice for fire setting, with some larch and pubescent birch. Specific choices were made regarding the most suitable wood for the task (Barge and Talon, 2012a,b). The pyro-technologies associated with mining go beyond smelting; the production of ceramics, cooking, domestic heating, are also activities that required significant quantities of wood (Cattiglia and Rossi, 1995).

Fig. 7 The Copper mine at Saint Véran, French Alps. Photo K. Walsh.

The receding treeline

From the Late Neolithic onwards, the depression of the treeline with the replacement of trees by pasture occurred across the Alps. Although there was little human impact above 2000 m, Bronze Age people developed high elevation areas for their agro-pastoral system. At 2265 m in the northern Swiss Alps, the treeline descended during the Bronze Age. Multiple lines of evidence point to the critical role of people in these landscape changes (Lotter et al., 2006). This was part of a broader trend of opening the alpine landscape, as seen in southern Switzerland (Hofstetter et al., 2006). In western Austria, human impact on woodlands during the Middle Bronze Age was enough to alter the botanical composition of spruce-fir woodland. Charcoal analyses from an altitudinal transect (1700–2700 m) in the northern French Alps demonstrate that vegetation was increasingly disturbed by human impacts from the mid-Holocene onwards (Carcaillat and Brun, 2000). The treeline also descended in the central Eastern Alps at c. 2000 BC (Nicolussi et al., 2005). At high elevation in the southern French Alps, stone pine forests were gradually replaced with larch and spruce from the Neolithic to the Bronze Age (Ali et al., 2005). This change in forest composition was driven by fire events most likely set by people clearing areas for pasture (Fig. 8).

Mountain erosion dynamics

This period also saw increased erosion and landslides, at least in part caused by forest clearance and associated grazing and mining activities. Evidence of these geomorphic changes has been found in the Dolomites, the Maritime Alps, and the south-central Italian Alps (Borgatti and Soldati, 2010).

Landscape changes during this period also manifested themselves via changes in the geomorphic system; changes in part caused by the reduction of forest cover, associated grazing and mining activities, all played their roles. Also, the start and the Late Bronze Age (2200 and 1200 BC) witnessed periods of climate change. In the Dolomites, there was a significant increase in landslides during the Bronze Age; in fact, higher numbers of landslides than any subsequent period (Borgatti and Soldati, 2010). At Lac Petit at 2200 m in the Alpes-Maritimes, a phase of reduction in vegetation cover and significant erosion was centered on 2200 BC (Brisset et al., 2013). Pollen from species indicative of meadows suddenly spiked, and its correlation with a phase of substantial erosion suggests direct links between these processes. The proxies from Lake Ledro (southern-central Italian Alps) reveal a significant rise in the lake level at c. 2500 BC, a consequence of climate change and human activity, the period between 2200 and 1000 BC saw a significant increase in erosion (Magny et al., 2012; Simonneau et al., 2013). Undoubtedly, this was a consequence of the combined effects of climatic variations, but also the exposure of more extensive areas of soil after forest clearance by people. In the northern French Alps, around Lake Verney (2188 m, Petit St Bernard Pass), the combination of increased hydrological activity and the beginning of pastoral activities during the Bronze Age (2350 BC) also led to a change in vegetation cover and an increase in erosion, which disrupted the soil system (Bajard et al., 2017a,b). These human activities are considered as the roots of regressive soil evolution. Farther north, at Lake Anterne (2060 m), a tipping point, characterized by an increase in flood deposit thickness and frequency, as well as erosion of deep soil-horizons, was recorded from 1450 BC (Giguet-Covex et al., 2011 Fig. 12). The identification of low levels of sheep DNA and the significant increase in *Plantago* DNA contemporary with these sedimentological processes suggests a human-triggered erosion (Giguet-Covex et al., 2014; Pansu et al., 2015). However, these erosion processes were also probably amplified by a climatic degradation as suggested by the glaciers advances (Kuhlemann et al., 2008; Ivy-Ochs et al., 2009; Le Roy et al., 2015). In the western Swiss Alps, phases of higher landslide frequencies associated with human-triggered vegetation changes were also recorded during the Bronze Age (1700 BC) (Dapples et al., 2002).

Bronze Age 2400 - 1000 BC

University of York.

Iron Age

Climate

Much of the Iron Age (c. 800–200 BC) was characterized by climatic cooling (Fig. 4), and in many areas, increased precipitation (Van Geel et al., 1996). Alpine lake levels rose from 750 to 350 BC. Climatic cooling led to the advance of many glaciers (Holzhauser et al., 2005). These changes shortened the growing season. A reduction in farming activities is recognized in some records. Despite climatic deterioration, mining activities increased during the Early Iron Age. Therefore, many economic activities increased, causing increased environmental impacts (Anreiter et al., 2009).

Changes in pastoral systems and impact on the landscape

In the South Tyrol/Italian Alps, the early Iron Age (referred to as the Hallstatt period (c. 800–600 BC)) saw a decline in human activity, perhaps as a consequence of climatic deterioration. However, during the later Iron Age (La Tène Period—fifth to first centuries BC), pastoral activity increased (Putzer et al., 2016). In some areas of the Tyrol, this level of human activity was not seen again until the Middle Ages (Heiss et al., 2005). Research in the Eastern Alps reveals increased farming, reaching the higher elevations. The dominant crops were barley, emmer wheat and spelt (Schmidl et al., 2007).

The forest at a site in the Ötztal Alps started to disappear after 550 BC, and pollen from cereals and other food crops starts to appear. At the Lagaun, Schwarzboden, and Penaud mires (2180, 2150, and 2330 m respectively). A site situated at 2150 m shows evidence of forest clearance from about 850 BC, the area emerging as pasture. This pasture remained intact to the end of the Roman Period (Festi et al., 2014). There was significant erosion at the site from 950 to 550 BC, perhaps because of climatic deterioration. In the Italian central Alps, the practices that started in the Bronze Age continued, the evidence for an increase in grazing is mirrored by an increase in charcoal (suggesting burning) from the immediate area (Moe et al., 2007). In the Leventina Valley (southern Swiss Alps) the Iron Age did not see a significant increase in human activity (Jacquat and Della Casa, 2018), although a diagram from the Fimba Valley does show a late Iron Age peak in microcharcoal (Dietre et al., 2014). Moreover, the earliest evidence for dairy production is found in Engadine, from organic residue analyses on potteries dating to the early Iron Age (Carrer et al., 2016). In the central Swiss Alps, at Hinterburgsee (1515 m asl), the first signs of human-triggered forest clearing began at ~450 BC (Heiri and Lotter, 2003).

A regional erosion signal for the NW Alps from Lake Bourget (France) comprises a geochemical signature (K/Ti ratio) that suggests two phases of erosion with a sub-alpine origin, erosion that may well have been caused by pastoral activities (Arnaud et al., 2012). For the Late Iron Age, this assumption is supported by the detection of cow and sheep DNA associated with the

beginning of a new phase of erosion. This record coming from the sediments of Lake Anterne, part of the Lake Bourget catchment (Giguet-Covex et al., 2014). Also, in the Lake Bourget catchment, but at a lower altitude, pollen and DNA records from Lake La Thuile (874 m asl), reveal the presence of *Plantago* and *Rumex*, i.e., indicators of pastoral activity. At Lake Verney (2188 m asl.), in the Tarentaise area, sheep DNA is also present in sediments dating to the Late Iron Age (Bajard et al., 2017b). At Lake Anterne there is also an interesting intersection between the sedimentary DNA evidence and archaeological data where the Late Iron Age animal DNA signal seems to be contemporary with the first occupation of a cabin around the lake (data from P.J. Rey in Giguet-Covex et al., 2014). An enclosure found next to the cabin might also have been used during this period.

In the southern French Alps, regional climatic variations influenced alpine ecology and possibly, economic practices. Unlike the Bronze Age, there are very few archaeological structures at high elevation in the southern French Alps. Deforestation took place across all mountain zones. Plant species indicative of human activity fluctuated during this period (Walsh et al., 2014) (Fig. 9).

Mining and impact on alpine environments

The Early Iron Age saw witnessed the expansion of mining in the Alps. Mining brought a reduction in forest and woodland as well as soil and water pollution that damaged the environment of certain areas. However, the fossil record is too scattered to allow the identification of specific impacts. An increase in charcoal at 1120 m in the Austrian Tyrol, suggests increased mining in the area (Breitenlechner et al., 2010). Salt mining became important in Austria, with important mines at Hallstatt (Kern et al., 2009) (Figs. 10 and 11). Charcoal analysis from a copper mining area in the Tyrol suggests that Early Iron Age miners chose coniferous wood for fire-setting.

The Roman Period

The Roman period in the Alps witnessed a radical change in the way farmlands were organized; however, this did not significantly change the level of human impact on sub-alpine and alpine ecosystems. Some regions of the Alps witnessed an increase and others, a decline in human activity.

Climate

At the start of the Roman period (1st century BC to 1st century AD), the climate underwent relative warming (Fig. 4). Proxy data from 1791 m in Switzerland suggests that the period from 15 BC to AD 120 was characterized by moderately warm temperatures,

Fig. 9 Cartoon reconstruction of a typical altitudinal section dated to the Iron Age. A period characterized by variation in the level of human impact across the Alps, but relatively few examples of significant pastoral pressure on high altitudes. Adapted, with permission, from Richer, S. (2009) *From pollen to people: the interaction between people and their environment in the mid- to high- altitudes of the southern French Alps*. University of York.

with some temporal variability (Stewart et al., 2011). This Roman climatic optimum may have been critical in facilitating Rome's success, with Alpine mountain passes possibly remaining open for much of the year during the climatic optimum (Hyde, 1935). Glaciological data from the Swiss Alps indicates that some glaciers were less extensive than they are today (Holzhauser et al., 2005).

Changes in pastoralism and impact on the landscape

Pollen records from areas either side of the Alps suggest increased agricultural activity during the early Roman Period. However, the South Tyrol saw increases in arboreal pollen, suggesting the reestablishment of forest (Heiss et al., 2005). In some areas, such as in the Southern Swiss Alps, agricultural activity remained steady until the end of the Roman Period (Della Casa, 2018). High-elevation pastoralism persisted throughout the Roman Period in the South Tyrol/Italian Alps, while alpine regions forests were re-established (Heiss et al., 2005). In the Italian Alps, all elevational zones were exploited during the Iron Age, but the Roman Period saw woodland recovery (Moe et al., 2007).

Ancient DNA analyses from Roman Period sediments in alpine lakes in the French Alps reveals significant increase in the number of sheep and cattle pastured at c. 2000 m (Fig. 12) (Giguët-Covex et al., 2014; Bajard et al., 2017a,b) and even as high as 2443 m asl at the important Savine pass between France and Italy (Sabatier et al., 2017). These activities, which might reflect the development of a trade with Rome (Giguët-Covex et al., 2014), lead to significant increases in erosion and substantial degradation of the soil resources (Giguët-Covex et al., 2014; Pansu et al., 2015; Bajard et al., 2017a,b).

In the southern French Alps, there is little evidence to suggest a dramatic change in the “natural” environment during the Roman period. Palynological research at lower elevations suggests the development of a heterogeneous, mosaic landscape. Certain areas were heavily exploited while other areas saw the reestablishment of woodland (Fig. 13). Cultivated trees such as walnut, chestnut, and even olive emerge. Perhaps there was pasturing at lower elevations in woodland. In some higher areas, the reduction in woodland may well have been related to mining, based on an increase in lead in sedimentary records (Segard, 2009; Py et al., 2014). Perhaps relatively accessible high-elevation landscapes witnessed increased human activity, such as in southern French Alps where zones around the Lac de Lauzun were exploited for pasture (Ponel et al., 2011).

Mining

There is surprisingly little evidence for mining in the Tyrol during the Roman period (Breitenlechner et al., 2010). Roman period mining may have occurred in the southern French Alps, although the only evidence is the change in lead content and isotopic signature in a peat bog. In fact, woodland may well have re-established itself in the sub-alpine zone during the second half of this period (Py et al., 2014). Several lake sediment cores in the North Western Alps also revealed peaks in heavy metals, notably lead, possibly from mining (Arnaud et al., 2006; Guyard et al., 2007; Giguët-Covex et al., 2011; Thevenon et al., 2011; Bajard et al., 2017a). In the Alpes-Maritimes, there is also some archaeological evidence for mining (Morin et al., 2007).

Medieval to Post-Medieval Periods

Climate

Based on evidence from multiple paleoclimatic proxies, the medieval climatic history of the Alps includes three different phases. First, the Late Roman-Early Medieval climatic deterioration centered on fourth-fifth centuries, second, the climatic optimum of the eighth-ninth centuries, and finally the Little Ice Age between 14th and 19th centuries (Buntgen et al., 2011).

Changes in pastoral systems and environmental consequences

In the high-elevation areas of the northern Swiss Alps, the early medieval period saw the recovery of the forest after the fall of the Roman Empire. In some areas, it is clear that grazing also declined (Wick et al., 2003). During the High Medieval Ages, alpine farmers developed clearings as part of the summer-farming system. The presence of *Potentilla* pollen signals this activity. During the Little Ice Age, increased soil instability across alpine slopes probably contributed to decreased human activity and concomitant reforestation (Röpke et al., 2011). In other parts of the Swiss Alps, the start of the trajectory towards the modern landscape began in the High Medieval Period, with extensive forest clearance (Wick et al., 2003). In the Silvretta Massif (Switzerland/Austria), a significant increase in the quantities of microcharcoal reveals human impact. While an increase in coprophilous spores represents increased livestock grazing areas during Medieval and Modern Times (Dietre et al., 2014). Evidence from the sub-alpine zone of the southeastern Swiss Alps (c. 1800 m) suggests that the landscape was open, with much of the forest cleared, by c. 1450 AD (Gobet et al., 2003) (Fig. 14).

In the Italian Alps, proxy-data suggests a phase of reforestation during the 14th century, interpreted as a downturn in human activity caused by the Black Death, a phenomenon seen in many areas of the Alps. Human activity subsequently increased, with another downturn during the Little Ice Age (Joannin et al., 2014).

In the northern French Alps, from 1000 AD, intensive pastoral activities developed across the “Alpages” and Montane zone. Interestingly, lake sediment DNA analyses reveal a change in livestock farming practices with the decrease of sheep in favor of cowherds, probably related to the development of cheese production (Fig. 12) (Giguët-Covex et al., 2014; Bajard et al., 2017a,b). In the Montane zone cereal crops significantly increase from 450 AD and triggered a strong degradation of the soils (Bajard et al., 2017a,b). From 1000 AD, this soil erosion decreases with the development of a diverse culture of fruit trees, including (pears, walnuts, plum or cherries, and grapes). Grapevine disappears due to the colder conditions during the LIA (Fig. 12).

In the southern French Alps, human activity in the sub-alpine increased during the medieval period (Fig. 14). Mining from the 10th century onwards caused a continued impact on forests (Fig. 15). Mining communities required wood and timber in significant quantities (Py et al., 2013). The High Medieval Period also witnessed an increase in pastoral activities, and this contributed to changes in vegetation across the sub-alpine zone. Several Medieval stone structures have been found in these pastureslands (Fig. 16). This activity continued into the 17th century, with tree-cover only restabilizing itself in the last 150 years or so.

Fig. 12 Lake sediment DNA records from the northern French Alps. The DNA metabarcoding analyses provide the animal composition in the Alpagoes around the lakes Savine (Sabatier et al., 2017), Verney (Bajard et al., 2017b), Anterne (Giguët-Covex et al., 2014) and La Thuile (Bajard et al., 2017a) (from the top to the bottom figure). For lakes Anterne and La Thuile, selected plant DNA, i.e., showing the forest (*Pinus* and *Abies* sp.), pastoral (*Plantago* sp.) and fruit tree evolution (*Pyrus* sp., *Prunus* sp., *Vitaceae*, *Juglandaceae*) are also presented (Pansu et al., 2015; Bajard et al., 2017a).

During the 18th and 19th centuries, there was of course variation in landscape trajectories, although broad trends were common across many valleys. Mining was intense in those areas where minerals were present. Pastoral activity was at its most intense across much of the Alps, with forest often depleted, leading to environmental problems, especially erosion. In some French alpine regions, cheese-production, often linked to large collective dairies, became important (Rosenberg, 1988). Provençal transhumance increased during the 19th century with a concomitant increase in population. The impact on the landscape resulted in state-level laws and regulations, including the Forestry Code in France. This period of intense activity took place despite the Little Ice Age, a climatic phase that appears to have ended relatively quickly in the Alps, with glaciers starting to retreat from the mid-19th century; a consequence of temperature increases exacerbated by industrial black carbon (Painter et al., 2013).

Depopulation was common across many valleys during the 20th century, although long-distance transhumance, now coupled with tourism, started to develop (Rosenberg, 1988). New European regulations and the development of protected regional and national parks have helped conserve and promote the pastoral activities and the maintenance of rich meadows and traditional forms of agriculture (von Glasenapp and Thomson, 2011; Schermer et al., 2016). However, at the same time, ski resorts with all of their infrastructure requirements have had a significant impact on the ecology and geomorphology of many valleys (Arnaud-Fassetta et al., 2005; Barni et al., 2007; Patthey et al., 2008). What is clear, is that the heterogeneity of these 21st-century biomes is at a tipping-point along a complex trajectory whose origins lay with the first incursions of hunters and pastoralists many millennia ago.

Abstract

Alpine ecosystems account for c. 3% of terrestrial habitats yet, along with adjacent mountain systems, provide water resources to nearly half of the world's human population. Approximately 20% of humans live in or near mountain areas, making it inherently important to understand contemporary impacts on these systems. Here, I review literature regarding contemporary and projected human impacts on alpine ecosystems, including the direct and indirect impacts of human-induced climate change on alpine plant, animal, and soil communities. I also discuss the influence of recreation and tourism, grazing, and other land use changes including the introduction of nonnative and invasive species in alpine systems. I conclude with management implications as well as future areas of research needed to better understand changes to these systems.

Changing Alpine Systems

Mid-latitude and polar alpine species are highly adapted to climatic factors that largely determine the biotic composition and distribution of plant and animal communities (Nagy and Grabherr, 2009). This includes low mean annual temperatures during a short summer growing season, limited moisture availability largely determined by snowmelt from winter precipitation, high levels of solar radiation, and large microclimatic variability across relatively short distances on the order of centimeters to meters (Körner 2003). Conversely, tropical alpine areas experience year-round growing season temperatures daily and are characterized by large diel temperature changes from day to night (Rundel, 1994; Buytaert et al., 2011).

Minimum temperatures have increased approximately 2 °C in alpine systems worldwide over the past three decades and have been accompanied, on average, by decreases in precipitation (Beniston et al., 1997). However, changes have varied as a function of regional climate controls (Beniston et al., 1997; Stocker et al., 2013). For example, high elevation sites in the Rocky Mountains of Colorado have experienced an increase in mean winter temperatures of 0.09 °C each decade since 1979, all of which were greater than changes observed across the entire state (Clow, 2010). At the same time, precipitation and snowpack have increased during spring months at high elevation sites (Mote et al., 2005). Additionally, recent climate warming has been attributed to major changes to alpine portions of the cryosphere including permafrost and glaciers (Paul et al., 2004; Liu and Chen, 2000). For example, major permafrost shifts have been observed on the Tibetan Plateau, including upward movements of 50–80 m. These changes have been observed in addition to range contractions as large as 1–2 km northward in the last few decades of the 20th century (Cheng and Wu, 2007). Cryosphere changes also include the rapid retreat of and water loss in alpine glaciers (Xu et al., 2009; Huss et al., 2010): a total loss of 18% of glacier area occurred across more than 900 alpine glaciers between 1985 and 1999 alone (Paul et al., 2004). Overall climatic changes in alpine systems have been characterized as having greater interannual variability than those observed in other systems around the globe (Beniston et al., 1997), leaving some to predict that alpine systems will experience some of the highest levels of warming globally while also showing responses to change before other terrestrial systems (Cannone et al., 2007).

Human impacts on future alpine climates are expected to be the direct result of increases in atmospheric concentrations of CO₂, which will lead to changes in temperature and precipitation (Winkler et al., 2019). A doubling of CO₂ will lead to increases in temperatures that are elevation-dependent and will lead to pronounced warming at higher elevations. If CO₂ concentrations triple, monthly rainfall may increase in alpine systems, though these changes will likely be small (up to 6% in one model; Burkhardt, 1999). However, regional models project decreases in winter precipitation falling as snow and an increase in winter precipitation falling as rain (Solomon et al., 2007). These coupled changes in temperature and precipitation will subsequently influence snowpack persistence and the timing of snowmelt, which, in turn, will impact growing season length, productivity, and biogeochemical cycling in alpine systems worldwide (Stewart, 2009; Winkler et al., 2016a).

Changes in alpine soils with respect to climate change will have substantial impacts on overall ecosystem performance since soils play an important role in structuring alpine vegetation (Körner, 2003). Soil microclimates, in particular, influence water movement

and nutrient cycling, and, as a result, species distributions and community composition (Graham et al., 2012). Given expected changes in snowmelt patterns, subsequent changes in soil properties and nutrient availability are also expected. Experimental warming on the Tibetan Plateau found that permafrost degraded with warming, accompanied by decreases in soil organic matter (Wang et al., 2006). Colder, higher-elevation alpine sites can have coarser soils and, as a result, less plant-available nitrogen (N) and higher soil pH than warmer, lower-elevation sites (Huber et al., 2007). Thus, climate warming has the potential to increase N availability as these higher elevation sites become warmer, thereby shifting ecosystem productivity (Brooks et al., 2011). Warming experiments have revealed distinct temperature effects on N cycling in alpine systems. Changes include increased N mineralization rates and net nitrification rates (Bai et al., 2013), increases in labile carbon and microbial biomass (Rui et al., 2011; Peng et al., 2016). Studies have also produced varying responses in overall soil N availability, including no change in available soil N (Wang et al., 2012) and increases in plant-available soil N with warming (Winkler et al., 2019). Overall, shifts in N availability may act as a feedback to plant responses but such changes are likely to vary by species, leading to shifts in community structure, diversity, and ecosystem productivity (Farrer et al., 2015; Alatalo et al., 2015).

Alpine Species Responses to Change

Alpine plant species are expected to respond to warming by growing taller as temperature limitations are alleviated (Walker et al., 2006). However, warmer temperatures are expected to influence snowmelt timing, which may negatively impact plant species by increasing their exposure to early-growing-season frost events (Wipf et al., 2009; Sierra-Almeida and Cavieres, 2010). These responses are also expected to vary by species (Sierra-Almeida et al., 2016). More complex phenological responses to warming are expected in alpine plants given the oftentimes tight coupling of seasonal growth initiation and duration to snowmelt (Winkler et al., 2018). As a result, most studies have found an advance in the timing of flowering in response to an advance in snowmelt timing (Steltzer et al., 2009). Similar phenological results have been observed in response to warming (Hovenden et al., 2008; Gimenez-Benavides et al., 2011).

However, whether temperature changes and snowmelt timing will be large enough to advance flowering remains unknown (Petraglia et al., 2014), and whether plants will be able to overcome the potential indirect effects of warming is also unresolved, including decreased available moisture and earlier senescence in response to advanced snowmelt and warmer growing season temperatures (Gimenez-Benavides et al., 2011; Ernakovich et al., 2014). Decreased stress under warmer temperatures may increase competition among plant species (Schöb et al., 2012). That said, some studies have found that facilitation among alpine plant species will remain an important process in a warming alpine environment (Cavieres and Sierra-Almeida, 2010; Anadon-Rosell et al., 2017). Additional research is needed to better understand plant-plant interactions in changing alpine systems.

Changes in alpine plant diversity, including those linked to recent climate warming, have generally found increases in alpine diversity over the past 25–100 years (e.g., Grabherr et al., 1995; Gigauri et al., 2013). At the same time, alpine plant community composition, though perhaps richer, has also shifted in recent decades and has likely done so in response to warming (Pauli et al., 2007). This matches predictions from experimental warming studies in alpine systems around the globe, though there is variability in how individual species or functional groups will respond (Kudo et al., 2010; Wahren et al., 2013). Long-term studies have in some cases revealed that recent warming explains a majority of the variation in changes in alpine species abundance (Soudzilovskaia et al., 2013). Some of these compositional shifts are likely the result of individual species migrating in response to historical climate change (Grabherr et al., 1995; Lenoir et al., 2008). For example, more than a third of 125 species have migrated at least 100 m higher than their previously reported upper range limits recorded 100 years ago (Frei et al., 2010). Some species have disappeared from their historical lower elevation limits with simultaneous increases in abundance at their upper-elevation limit that now experiences warmer temperatures (Klanderud and Birks, 2003). Such shifts have accelerated in recent decades (Rixen and Wipf, 2017) but have not been synchronous across species within a given community (Cannone et al., 2007). Additionally, alpine floral responses to warming can also be influenced by other climate changes including drought, wildfires, and nitrogen deposition (Lenoir et al., 2010; but see Williams et al., 2009). For example, plant responses to experimental warming in an alpine heathland in Australia revealed differential responses to warming in unburned areas resulting in increased forb and shrub cover and decreased grass cover, while warming in burned areas reduced grass and forb cover and facilitated a rapid expansion of shrub cover (Camac et al., 2015). These results highlight that many of the responses observed or predicted in alpine systems will be the result of complex, oftentimes interactive, processes.

Climate warming impacts have also been manifest in alpine animal species (e.g., Beaver et al., 2016; Rubidge et al., 2012). Perhaps the most well-documented changes have been to iconic pika species including the American pika, *Ochotona princeps*, which has experienced major range retractions with climate warming in recent decades (Mathewson et al., 2017; but see Millar and Westfall, 2010). Molecular evidence and ecological modeling show that recent demographic declines across all *O. princeps* lineages suggest that the species will experience declines in genetic diversity with continued climate warming (Galbreath et al., 2009). Alpine arthropod communities are also at risk due to climate change (Gobbi et al., 2006; Hågvær and Klanderud, 2009) and this has large implications since arthropods account for a large part of alpine fauna communities that are structured by strong climatic relationships (Edwards, 1987). However, alpine arthropod responses to warming can vary substantially by taxonomic order (Hågvær and Klanderud, 2009). For example, a snow removal experiment in Australia found that of the Collembola, Araneae, Acari, and Coleoptera orders that accounted for 95%–98% of the arthropod diversity at this site, Collembola was most sensitive to early-season snow removal and that both positive and negative responses were observed within the order (Slatyer et al., 2017). Furthermore,

changes in alpine plant species composition and cover can also have direct effects on faunal communities that depend on them, and vice versa (Rasmann et al., 2014).

Novel Species in the Alpine

Human-induced climate warming has also been linked to an increase in plant and animal invasions and encroachment in alpine systems around the globe (McDougall et al., 2005). This remains separate from the multitude of intentionally introduced non-native species in alpine systems around the globe (see grazing section below; Donald et al., 2001; Wilson and Lee, 2010). These unintended invasions include the fly *Rhagoletis completa* in Europe, which consumes alpine plants during the fly's larval stage (Aluja et al., 2011), the invasive dwarf bamboo *Sasa kurilensis* in northern Japan (Kudo et al., 2018), and a dandelion in the Chilean Andes (Molina-Montenegro et al., 2012). Invasions in alpine ecosystems have serious implications for native species because they can cause reductions in available resources, changes in productivity and cycling, as well as lead to pollinator disruption (McDougall et al., 2011; Kašák et al., 2015). It is possible that human transport has mediated some of these invasions (McDougall et al., 2005) but it is also likely that the amelioration of historically-harsh climatic conditions has allowed invasives to colonize alpine systems (Pauchard et al., 2009; Winkler et al., 2016b).

A similar framework of ameliorated microclimatic conditions has been used to understand shifts of the treeline ecotone into historically alpine-restricted zones (Kharuk et al., 2009; Kueppers et al., 2017). This line of investigation has also been used to document and understand woody encroachment above historic treeline elevations and into alpine areas that were previously grass- or forb-dominated (Brandt et al., 2013; Gartzia et al., 2014). While some studies have shown positive growth and establishment of tree seedlings above the traditional treeline (e.g., Danby and Hik, 2007) others have shown that warming can lead to decreased recruitment at and above treeline, likely owing to coupled soil moisture changes (Hofgaard et al., 2010; Kueppers et al., 2017). Together, these shifts in treeline and woody species abundance above treeline have serious implications with potential to disrupt carbon storage and nutrient cycling across the globe (Greenwood and Jump, 2014).

Grazing and Human Development Impacts on Alpine Systems

Livestock grazing is common in many alpine regions of Asia, Australia, Europe, and South America (Fig. 1; Nagy and Grabherr, 2009). Grazing can alter landscapes and can also influence alpine-species responses to climate change (Scherer and Pickering, 2005;

Fig. 1 Examples of the direct human impacts on alpine ecosystems, including cattle grazing (top left), a skier on the alpine slopes above a ski resort (top right), hikers and hiking trails (bottom left), and the basecamp in Nepal that marks the start of the climb up Mount Everest (bottom right).

Luo et al., 2010; Hope, 2014). Warming, combined with continued grazing in some of these alpine systems, may lead to declines in vegetation productivity and overall forage quality for livestock (Klein et al., 2007). There are also direct conservation issues related to humans controlling native alpine populations to increase forage value for livestock and other domesticated animals. Perhaps most notorious is the poisoning of the Plateau pika, *O. curzoniae*, that has led to major population declines while simultaneously opening more forage opportunities for livestock (Smith and Foggin, 1999). Animals introduced for grazing are not the only groups to negatively impact native alpine species. In the case of New Zealand's introduced, invasive stoat, *Mustela erminea*, the native and endangered takahe, *Porphyrio hochstetteri*, and rock wren, *Xenicus gilviventris* are at major risk of predation and potentially extinction (O'Donnell et al., 2017). A similar story holds for the introduced house mouse, *Mus musculus*, and its impacts on native alpine plant and arthropod species (Wilson and Lee, 2010).

Climate change impacts on alpine aquatic species including freshwater invertebrates and amphibians have been exacerbated by human development of dams, canals, and introduced species (often for recreational fishing; Bradley et al., 2006; Tiberti et al., 2014). These human-caused changes have resulted in drastic declines in frog, microcrustacean, and native macroinvertebrate abundances and diversity in alpine lakes in the Sierra Nevada of California (Bradford et al., 1998). Similar declines have been observed in the Italian Alps (Tiberti et al., 2014) and the Canadian Rocky Mountains (McNaught et al., 1999). However, evidence points at the potential for recovery when invasive fish have been removed from some of these same alpine lakes (Donald et al., 2001), providing sound management implications if conservation measures are prioritized. Conservation of freshwater insects in alpine lakes has been identified as a potential issue in response to hydraulic stress resulting from dams and canals used to control water resources (Rossaro et al., 2006). Given that more than half of the world's human populations depend on alpine and montane water resources (Viviroli et al., 2011), alpine freshwater invertebrates not only demonstrate the direct human impacts related to damming, canalization (Rossaro et al., 2006), and invasive species impacts (Magnea et al., 2013), but can also be utilized as indicators of environmental change in the rivers and lakes where they occur (Catalan et al., 2006).

Recreation and Tourism in Alpine Systems

Visitation to protected alpine areas is expected to increase as a direct response to climate change increasing periods of desirable weather for tourism (Fig. 1; Richardson and Loomis, 2005). This has serious management implications, as recreational activities have been shown to directly impact alpine floral (Pickering and Hill, 2007) and faunal communities to varying degrees (Monz et al., 2010; Negro et al., 2010). For example, a study in an undisturbed alpine zone in Tasmania found that trampling alpine plants led to declines in vegetation cover after an environmental threshold of 200 steps on a given point occurred (Whinam and Chilcott, 2003). The study also found that the threshold varied as a function of plant type, with woody shrubs and grasses susceptible to damage with fewer steps whereas alpine cushions were tolerant of up to 500 steps. Also, watersheds in the Himalaya have been shown to be negatively impacted by the increasing tourism in the area (Fig. 1; Nepal, 2003; Byers, 2005).

Alpine faunas have been shown to be equally susceptible to recreation impacts (Roland et al., 2007; Patthey et al., 2008). A global meta-analysis found that alpine birds were most susceptible to the negative impacts of winter recreation (i.e., skiing) and mammals and arthropods were also susceptible to a lesser extent (Fig. 1; Sato et al., 2013). Interestingly, this meta-analysis also identified a number of cases that showed no effect on faunal communities but an overall decline in animal species richness, abundance, and diversity was observed in ski resort areas (Sato et al., 2013). However, some research has modeled decisions tourists make and identified potential management practices that would minimize human-wildlife interactions in alpine systems (Coppes and Braunsch, 2013).

Conclusions and Future Directions

Humans are altering alpine systems worldwide through impacts related to grazing, development, and tourism, and also climate change. These perturbations are already pushing these ecosystems into novel states. With recent impacts on alpine floral and faunal diversity and distributions, new communities are emerging with clear, negative impacts on alpine species. Many of these responses are being driven by changes to the abiotic and microclimatic controls in these systems. For example, the loss of alpine glaciers will have dramatic effects on the flora and fauna of alpine environments, in addition to the human populations that depend on the resources they provide (Xu et al., 2009; Huss et al., 2010). Although these changes will likely have irreversible effects on many alpine species (Haeberli and Beniston, 1998), effective management efforts have the potential to mediate at least some responses to change and can curtail previous recreation and development impacts (Morrison and Pickering, 2013). However, the challenge of documenting changes that have already occurred in alpine systems and predicting future changes remains. Nonetheless, the global importance of alpine systems should outweigh the difficulties that may be necessary to overcome in order for managers and public and private stakeholders to effectively manage and conserve these valuable ecosystems.

Abstract

The alpine biome of North America is responding to ongoing changes in climate, nitrogen deposition, invasive species, and local human activity. The response to widespread climate change is complicated by heterogeneity in abiotic interactions and biotic interactions. Interactions across spatial scales and time lags limit understanding. The other three drivers are spatially concentrated. Terrestrial ecosystems are more affected by climate change and local human activities, while aquatic ecosystems bear the brunt of impact by nitrogen deposition and invasive species. Because of the heterogeneities and time lags, changes in biodiversity are likely to be limited to marginal ecosystems, and changes in carbon balance will be locally important but small relative to global flux. Water resources from alpine areas may change significantly, but due to the direct effects of climate, not through change in the biome.

Alpine Change

The alpine biome in North America is changing in response to four major forces of global environmental change: climate change, nitrogen flux, invasive species, and habitat destruction and deterioration. The alpine biome is climatically defined as high elevation zone where too little energy or heat exists to support trees but enough to prevent permanent snow and ice. The biome has varied terrestrial and aquatic ecosystems. The vegetation of terrestrial ecosystems are primarily alpine plant communities, which are dominated by forbs, sedges, and grasses and include a range of moss and lichen in addition to often prostrate shrubs and some “subligneous” plants (not quite forbs or woody but not strictly herbaceous). The terrestrial ecosystems are heterogeneous, with different plant communities within small areas that vary because of differences in soils and especially in water availability. The aquatic ecosystems are headwaters lakes, ponds, and streams and often freeze completely in winter. The aquatic ecosystems differ geographically but are simple in comparison to other aquatic realms. Alpine wetlands can be transitional between the two major types but are so often seasonal that they are more closely associated with terrestrial plant communities. Secondarily, the “alpine” can extend to where scant soil or water limit trees at high elevation.

All four forces of global change are affecting alpine ecosystems of North America. Their importance varies overall and among the different ecosystems. Climate change is by far the most general and most studied driver of change in the alpine biome of North America. Nitrogen flux is spatially concentrated, and where it occurs it is relatively more important in aquatic ecosystems. Invasive species are few but can be locally important. Habitat destruction and deterioration are isolated to the immediate corridors of the few roads and many trails.

Climate Change

Expected Responses

Because the alpine biome is primarily delimited by cold climates, it is expected to be affected by global warming. However, impacts are uncertain. Because climatic gradients are steep on mountain slopes plant biogeography is spatially compressed, and the shift in climatic habitat may be within the dispersal ranges of species. However, the alpine biome cannot move upwards, and in many cases, the terrain existing at the highest elevations has no soil. Moreover, an upward shift in alpine treeline would reduce the area of the alpine. Even allowing for the colonization of now-bare areas or increased densities, the total area should decrease because mountain peaks are generally conical. Along with upward movement, areas such as saddles or cols that joined higher alpine regions could become tree-covered, further isolating the remaining areas of alpine vegetation. Moreover, many alpine plant species do not have the adaptations required for long-distance dispersal (Morgan and Venn, 2017).

Also, alpine biome areas may experience elevation-dependent warming (EDW) (Pepin et al., 2015), which would accelerate climate change impacts. Based on the observations, EDW is a climatic phenomenon in which high elevation areas increase in temperature more than other landscapes, e.g., warming 1.8 times more than the global average in the northern Rocky Mountains (Pederson et al., 2010). Other long-term observations of snow and ice also reflect rapid temperature changes in North American mountains (Fountain et al., 2017).

The current area of the alpine could decrease within decades. At a coarse resolution, Diaz and Eischeid (2007) calculated that the cold climate associated with the alpine biome will no longer exist in the continental United States, given the current trends in climate change. The true area of the alpine biome is not known, however, because delineating boundaries in steep terrain has been difficult (although current remote sensing could rectify this). Additionally, the potential upslope advance of treeline carries considerable uncertainty. Components of alpine vegetation might shift upslope, but the alpine is not zonally divided by elevation. Instead, topographic variation at all scales creates differences in energy, water, and soil resources that determine the habitats within which different types of alpine vegetation exist. Therefore, a simple upward shift of alpine community types is not expected, and change could be in a variety of directions (Malanson and Fagre, 2013).

In a thorough review of the effects of climate change on alpine limnology, Redmond (2018) primarily reported on expectations and complications, and some of these occur through interaction with other factors of global change, most notably nitrogen deposition and invasive species. Her expectations are summarized in Fig. 1.

Observed Responses

Some of these responses may now be visible. Settele et al. (2014, 317), as part of the IPCC process, reported that"

Fig. 1 Redmond's (2018) summary of the cumulative effects of climate change and other stressors on the function and community composition of alpine lakes. Redmond, L.E. (2018). Alpine limnology of the Rocky Mountains of Canada and the USA in the context of environmental change. *Environmental Reviews* 26, 231–238.

"There is high confidence that alpine systems are already showing a high sensitivity to ongoing climate change and will be highly vulnerable to change in the future."

Expectations led to the creation of alpine vegetation monitoring efforts. The most developed of these is the Global Observation Research Initiative in Alpine Environments network (GLORIA) (Grabherr et al., 2000). GLORIA was developed to extend the record from observations in the early 20th century and to extend similar types of observations across the globe to sites where a legacy of alpine vegetation data did not exist. GLORIA is a network of > 120 sites at which summit vegetation is monitored; summits are some of the harshest environments for plants and even slight warming might have distinct impacts in plant composition, phenology, and growth.

GLORIA includes sites in North America; 31 were established and four more proposed, but not all are continuing with the planned a 5-year schedule (Table 1). These observations are in their early stages and have not yet produced definitive results (e.g., in the Brooks Range, AK and in the Chic Chocs, Quebec; personal communication March 2019, J. Jorgensen and G. Fortin, respectively). In Glacier National Park, where some observations were made annually, the annual turnover in species composition was high (personal communication March 2019, D. Fagre), and 5-year change was substantial but not consistent in direction over 5 years (Malanson and Fagre, 2013).

More restricted monitoring has also yielded useful results. Lesica (2014) established plots for monitoring alpine vegetation change in Glacier National Park in 1988. Initial results of this project showed a shift toward drier vegetation types. Reporting observations through 2011, Lesica (2014) found declines in the cover of species with narrow, high-elevation distributions. However, absence of change predominated. For a broader study that included some of the same sites and again focused on species at the southern end of their ranges, Lesica and Crone (2017) reported decreases in populations for all six alpine dicots and three of six

Table 1 GLORIA projects underway or proposed (*) for North America. Note that some may no longer be operational (e.g., at Niwot Ridge, CO, vandals disrupted the project; personal communication, William Bowman)

monocots (plus two increasing and one unchanged). They attributed the inertia of monocots to their root systems being more adaptable to periods of drought.

For longer time periods, resurveys of earlier plots, or at least the same slopes, have been informative. For 88 plots established on Niwot Ridge, CO, Spasojevic et al. (2013) resurveyed them six times in 20 years and found that community change could be substantial. The degree of change varied with the type of alpine plant community, and some were temporary. Danby et al. (2011) reported increased diversity and evenness in alpine vegetation in the Canadian Yukon over four decades. Changes differed among sites, particularly with aspect, with the least amount of increase in richness but the greatest change in composition occurring on southwest aspects. Still, the overall change was attributed to an observed increase in mean annual temperature during the period between observations.

Changes in growth, phenology, and/or carbon flux have been observed following climate change or experimental manipulation (e.g., of snow cover, with consequent warmer subsnow temperatures) (e.g., Walker et al., 1995, 1999). Both observational (Wagner and Reichegger, 1997) and experimental (Galen and Stanton, 1995) studies of climate effects on flowering and seed development have yielded significant results. Intensive study in the southern Rocky Mountains has highlighted damage from earlier flowering due to subsequent frost and has established the timing of snowmelt as an important driver that is affected by climate change (e.g., Inouye, 2008).

Complicating Factors

Factors that complicate alpine biome response to warming and separate expectations from observations include abiotic drivers, biotic interactions, and spatial and temporal scale issues.

Abiotic complications

Alpine vegetation is found across a broad range of moisture conditions, and differentiation of plant communities may be related to water availability (Malanson et al., 2012; Winkler et al., 2016) in addition to temperature gradients (Elmendorf et al., 2012). The moisture conditions are largely controlled by topography at multiple scales (ranging from orographic precipitation/rain shadow effects to microtopographic rills). Even the details of microtopography across a few centimeters affect species composition and diversity (e.g., Rose and Malanson, 2012). Moreover, the variation in alpine communities is often weakly correlated with other abiotic variables (Suding et al., 2015). Thus, alpine vegetation varies over short distances and, because it is found in a wide variety of microclimates, responses to climate change may be habitat specific.

High elevation vegetation response to climate change is also profoundly affected by snow persistence. Snow affects alpine plants through thermal protection, water provision, effect on atmospheric deposition, and determination of the length of the growing season. Upward shifts in snow cover could lead to threshold effects more profound than the causal temperature changes. Many western North American mountains are relatively arid. Increased future temperatures, without compensating increases in precipitation, will drive these landscapes to greater aridity and have out-sized impacts on the current mountain vegetation that may be existing near their drought tolerance limits. Greater aridity will make snow beds, springs and other wet areas more important to some plants and generally increase the variability in moisture across the mountain landscape. Reduced snow persistence will likely change seasonality for alpine plants, shortening the growing season and lowering plant productivity (Ernakovich et al., 2014). Vegetation vulnerability to increased aridity will also be manifest in wildfire as an agent of disturbance in alpine areas where it has been rare or not existed before.

An example complication is for change in water resources in the northern Rocky Mountains, United States. In this region, snow is often relatively dry when it falls and easily redistributed by wind, from windward, convex slopes to leeward, concave slopes. It accumulates in "snow beds" that persist into summer long after other snow has melted (and in some cases are year-round features). As elsewhere, snow bed vegetation, growing near these features, is adapted to this water source and could be classified as wetland vegetation in some instances. Snow beds can change with climate change. Warmer summer temperatures or less winter precipitation will reduce snow bed area. Smaller snow beds hold less water. Changes in local hydrology or changes in the predominant wind direction could also reduce snow beds. In this case, Local vegetation type will become dominated by species adapted to drier conditions. Although aspects of this example do not occur everywhere (and snow beds are common even where snowfall is not so dry), warmer temperatures not accompanied by increased precipitation would lead to similar expectations more generally, and any shift of climate could change the niches expressed on an alpine landscape.

Soil differences can also complicate alpine vegetation response to climate change. Soils may differentiate plant communities, and their plant-soil interactions may vary (Buri et al., 2017). However, organisms involved in these relations range from bacteria to bears, which vary locally and regionally. A number of experiments on Niwot Ridge have shown an association between fine sediments and types of alpine communities (e.g., Forbis et al., 2004; Sherrod et al., 2005). Perhaps most notable has been the rapidity of overall change in the ecosystem. At fine scales, the rates of biome response to climate change may be affected by the soils in the context of microtopography (Suding et al., 2015).

In aquatic systems, the abiotic complications of climate change identified by Redmond (2018) included the variation in thermal variability with water body size and depth and glacial influences, in addition to the variation in the drivers of increased temperature and increased dryness. In the often fish-less waters, effects on plankton can be significant. Phytoplankton are expected to increase in productivity, with consequences for water clarity. On a size gradient, smaller water bodies (ponds) are expected to respond differently to climate change than larger ones (lakes). Although lakes might appear better buffered by their size, warming and drying would move them in the direction of ponds, which have distinctly different zooplankton biota. Alpine lake zooplankton have

less tolerance for warmer conditions to which pond zooplankton are adapted. With drying, shallower lakes could have greater penetration of UV radiation, to which some zooplankton are sensitive. Melting glaciers also complicate the responses to climate change. Increase meltwater inflow can reduce some of the impact of warming and drying, but could also be a source of organic pollutants stored in past years. At some point the loss of this inflow altogether could trigger major shifts in the ecosystems.

Biotic complications

Biological interactions in the alpine are well-recognized. Although competition remains important (Theodose and Bowman, 1997), the role of neighboring plants in modifying microclimate is greater relative to lower-elevation biomes (e.g., Choler et al., 2001). The implications for long-term dynamics are uncertain. Soil microorganisms further complicate edaphic conditions and affect plant communities relative to climate (e.g., Bueno de Mesquita et al., 2016).

Species diversity is relatively high over small areas for the level of productivity, but intraspecific variation is also common. This variation means that responses to climate change can vary among and within species and across habitats. Temporally, changing phenology in relation to climate change exhibits complicating factors (Walker et al., 1995; Inouye, 2008). Some phenological responses are habitat-specific or species-specific—or even vary within species. The degree of interannual variability could significantly complicate response to climate change. Such changes have been observed when plots are regularly monitored.

Spatial complications

The relative isolation of the distribution of the alpine biome in the mountains will affect responses to climate change. Because of isolation, the turnover rate in the absence of climate change should be low, so that observations may be useful. In the far north, the alpine biome merges with the arctic biome and the degree of isolation is less.

Suding et al. (2015) found that assessment of community stability was scale-dependent. Energy and water resources vary at fine scales in alpine environments (e.g., Saunders and Bailey, 1994), as does disturbance (e.g., Johnson and Billings, 1962). Malanson and Fagre (2013) found that GLORIA single summit responses were small when considered within a continental scale context.

Over larger scales heterogeneity matters modestly. For two intensively sampled regions, the Indian Peaks Area, CO (IPA) and Glacier National Park, MT (GNP), the range of difference in alpine plant community composition between the two regions was matched by the range within each (Malanson et al., 2011). The source of this variation is in the details of topography at multiple scales. While substantial differences in temperature regimes exist within the alpine zone in any mountain range because of elevation, aspect often creates as great a difference, given the potential differences in insolation at high altitude. Local heterogeneity is found in many places given differences in albedo and vertical structure within alpine communities, and differences in soil moisture could be equally important in maintaining cooler temperatures in daytime and perhaps warmer temperatures at night. At the largest scales, the differences in species composition may not be strongly related to current climates (Malanson et al., 2015a).

The biotic climate-related complications highlighted by Redmond (2018) for aquatic systems depend on the initial taxa in a given lake or pond (which differ), complicated primary productivity, and varying trophic structures with differential growth rates.

Temporal complications

Temporally, the alpine biome may exhibit considerable inertia in relation to climate change because many species are long-lived perennials and with broad ecological tolerances. Yet the extreme alpine environment is such that ‘noise’ in the ecological ‘signal’ is created by interannual variability from establishment quickly followed by mortality. Alpine communities may thus have a slow response in some species, masked by ‘noise’ from others. It is this individualistic set of responses that poses one of the greatest challenges for scientists attempting to assess alpine tundra as a sentinel for climate change and its impacts. Efforts to identify communities for monitoring (mountain summits or wet-turf sites) may need to be supplemented by a focus on individual species.

The extent of the alpine biome may have been much greater 20,000 years ago than it is now (Harris, 2007). Following current theory and work from island biogeography and habitat fragmentation, as area decreases and isolation increases, alpine regions should be able to support fewer species, but with a time lag known as “extinction debt”, i.e., in the smaller and more isolated areas, some species are doomed to eventual extinction as the lower equilibrium number of species is approached.

The consequences of disequilibrium for the alpine biome are that species may not occupy the area where they would have maximum fitness given their adaptations and their relations with other species. At an extreme, species could appear to be randomly distributed within the constraints of their adaptations. In that case, the alpine biome may have been in disequilibrium with climate for millennia, and current observations of the presence and abundance of species in relation to climate will not be useful for predicting responses to climate change.

Lastly, climate change is not linear and gradual. Natural variability, including decadal scale cycles, can create pulses of change in temperature, precipitation, and prevailing winds. Alpine biome change can thus be episodic.

Nitrogen Flux

Nitrogen deposition in alpine ecosystems occurs in areas that are downwind of urban and agricultural sources (Bowman and Steltzer, 1998). In North America, these are primarily in the Sierra Nevada and the Front Range in Colorado, where upslope winds countervailing the regional dominant airflow affect alpine regions. Much of the nitrogen deposition in the alpine biome occurs in

winter snowpack, and runoff carries it directly into alpine lakes and streams; a minimal ability for alpine plants to absorb nitrogen also contributes to this flux. Thus, aquatic systems are most strongly affected.

In the terrestrial ecosystem, alpine grasses are likely to be favored at the expense of forbs, and a shift in the composition and diversity of plant communities is possible. Dominance of grasses would likely lead to a decrease in diversity.

In the aquatic ecosystems this flux has led to changes in the algae and possibly among microorganisms. Eventual acidification is possible. [Redmond \(2018\)](#) noted N-deposition as a primary stressor that could interact with higher temperatures and shallower ponds to affect grazer populations as well as primary productivity. Again, a notable impact would be a decrease in diversity.

Other chemicals originating from human activities also reach the alpine biome. These include lead and mercury among heavy metals and organochlorides such as PCBs ([Bowman et al., 2002](#)). Some of these become concentrated at higher trophic levels, e.g., in fish, and thus become a hazard to consumers such as eagles, bears, and humans. This concentration can be increased by warmer temperatures.

Invasive Species

Invasive species are a minor problem in the terrestrial ecosystems of the alpine biome. In the northwestern United States, [Parks et al. \(2005\)](#) categorized 92 species in three alpine regions by their ability to invade with or without disturbance. Of these potential 276 targets, only seven could invade without disturbance. Worldwide, [Alexander et al. \(2016\)](#) reported fewer than 200 nonnatives in alpine biomes. However, they noted that the problem is likely to increase. Occurrences, and impacts to the aesthetic resource, are spatially concentrated along trails and roads. Even then, most of that change in resource will be hard to recognize. Work on invasive and native congener dandelions suggests that the former may be able to spread their combined coverage as well as replace the latter to some degree ([Brock et al., 2005](#)).

In alpine lakes, many of which had no fish in the past because of their isolation, stocking of trout—many nonnative—has changed these ecosystems. In some cases, the introductions of nonnative species eliminated species of native trout. Even the introduction of native trout to previously fishless lakes has consequences for other organisms, such as amphibians ([Knapp et al., 2001](#)). [Redmond \(2018\)](#) noted that such introductions changed the size structure of aquatic organisms, which would affect the overall aquatic ecosystem response to climate change.

Habitat Destruction and Deterioration

Few roads and fewer land use transformations occur in the alpine biome of North America. However, [Bowman et al. \(2002\)](#) identified recreation as the most serious direct threat to alpine environments. Little of this intrusion is directly motorized, with few roads in the alpine biome, but these roads provide easy access to the many trails. Where roads and trails meet, crowds can form and localized trampling is a concern. In some national parks, hiker density in midsummer can be similar to a busy city sidewalk. [Willard and Marr \(1970\)](#) noted the susceptibility of wetter ecosystems to trampling in Rocky Mountain National Park, and in a follow-on report, [Willard et al. \(2007\)](#) reported some recovery but concluded that even without further impact complete recovery might take a century. Even far from roads, popular trails and peaks can be crowded in the summer. Alpinists affect the feeding activity of grizzly bears (other than as meals) ([White Jr et al., 1999](#)). Some of the more prominent recreational effects are the construction of ski facilities ([Richard and Côté, 2016](#)), but the active skiers might also impact animal behavior. The larger effect associated with trails is the introduction of exotic species.

People have also grazed livestock in limited areas of the alpine biome in North America. While controlled grazing, especially of sheep, has had impacts in subalpine meadows, grazing above treeline was rare simply because it was less accessible, less productive, and unnecessary. Overgrazing by native herbivores with denser populations due to the loss of predators can, however, have ecological effects, but these are uncertain. Herbivore trampling is a localized and perhaps temporary effect, and such grazing is decreasing as more of the alpine is devoted to recreation and wilderness.

Consequences of Change

Biodiversity

A primary concern for the impacts of change in the alpine biome of North America is the loss of species. Observations to date indicate that such losses are not yet occurring, but any period of increased rates of change and the possibility of extinction debts results in the potential for loss. Of particular concern is the high number of endemic species in the biome ([Malanson et al., 2015b](#)), for which local extinctions would be global extinctions. Because of the heterogeneity of habitat at even local scales, however, the losses of species may be restricted to those that are specialized in the extremes of this biome: the wettest, driest, warmest, or coldest places—if, in their locale, the climate becomes drier, wetter, colder, or warmer, respectively. Given the larger trends, species adapted to relatively warm conditions should have the opportunity to move upward unless limited by space while being replaced by nonalpine species. Those adapted to the coldest habitats may have no viable local places to move. Drier- and wetter- adapted species could be threatened, depending on the direction of change in precipitation. All potential changes are highly uncertain and will depend on local conditions.

Losses of biodiversity may also be seen at higher trophic levels. Although the animals that inhabit the alpine at least some of the time range from grizzly bears to butterflies, those that are specialized are most threatened. Perhaps the most iconic of these is the pika (*Ochotona princeps*). While the loss of alpine vegetation will reduce the habitat for pika, climate change can have direct impacts as well. Although pika can die from heat stress, they also may be stressed by low temperatures where protective snowpack has been reduced; both stresses can reduce populations and lead to local extinctions (Beever et al., 2010; Smith and Millar, 2018). Equally visible but quieter, populations of alpine butterflies may also be reduced by warmer temperatures and more extremes events (Buckley and Kingsolver, 2012; Roland and Matter, 2013). The effects of such losses on other species in food webs are unknown, but interactions will cascade into other biomes; e.g., alpine summer-resident army cutworm moths form a substantial portion of the calories consumed by grizzly bears (White et al., 1998).

Water

Mountains are important sources of water for human uses. Whereas climate change in alpine regions is beginning to have significant impacts on water resources, such as the loss of glaciers, changes in the alpine biome per se that will affect hydrology are likely to be minimal. The replacement of alpine vegetation by trees could increase snow local snow retention, but this change is likely to be small and slow.

Carbon Flux

The carbon balance of the alpine biome is becoming negative. Increased carbon sequestration as a consequence of rising treelines, and thus the replacement of lower carbon storing alpine landscapes with trees, would not be a major change. A calculation can be made, based on numbers from the alpine area in the coterminous United States of 1.1% (Lugo et al., 1999) and assuming 2% for Canada and Alaska, differences in carbon storage from Grafius and Malanson (2015), and the current emissions levels from the International Energy Agency (IEA, 2019):

• North American alpine area (1.6%)	$0.30 \times 10^6 \text{ km}^2$
• 10% change over 100 year, assumed	$0.03 \times 10^6 \text{ km}^2$
• Subalpine-alpine difference	2300 T km^{-2}
• Total 100-year difference	$69 \times 10^6 \text{ T}$
• 2018 USA energy-related emissions of carbon	$4.8 \times 10^9 \text{ T}$

The 100 year increase in carbon storage resulting from a replacement of 10% of alpine biome by alpine ecotone trees would be approximately 7% of the current *annual* energy-related emissions of carbon by the United States. Moreover, warming climate would lead to greater respiration, which could be increased in areas with nitrogen deposition; areas with less snow cover may be the most dynamic, with a net output of $2.3 \text{ T km}^{-2} \text{ year}^{-2}$ (Knowles et al., 2019). Assuming these areas cover 10% of the alpine biome, their output would be $3.5 \times 10^6 \text{ T year}^{-1}$, or five times the potential carbon sequestration by rising treelines over a century.

Aesthetics and Recreation

The alpine biome is an important destination for hikers. The athletic and aesthetic experiences remain for those able and willing to venture away from popular locations. For many, however, the experience is deteriorating. The biome per se is largely unchanged, but the consequences of more people in the most crowded locations will inevitably lead more people to hike and camp slightly farther into the biome; these in turn will add to habitat deterioration, invasive species, and changes in the populations and/or behavior of native species.

Summary

Unforeseen changes are always possible. Ferrarini et al. (2017) have shown novel climates can create novel complications in alpine biome. The interactions of the major forces of change remain speculative but worrisome. The alpine biome in North America in the future will remain a valuable resource, especially in the most remote areas, but no areas will remain unaffected by change.

Abstract

Impacts of climatic and land use changes on alpine life zones of Asia are presented, reviewing the most current knowledge with a focus on cryospheric responses, biotic responses, and the alteration of land use patterns. Rates of climate warming in Asian mountain systems substantially exceed the global mean, leading to a significantly declining snow-covered area (SCA), to widespread decreases in area, length, and volume of glaciers, and to widespread permafrost degradation. Complex adaptations of mountain biota to novel combinations of bioclimatic and other site conditions are ongoing, including upslope expansion of distribution ranges, treeline dynamics, migration of invasive species, phenological shifts, and changes in primary production. These biotic responses will inevitably lead to modified structure, composition, and functioning of alpine ecosystems. Recently, globalization effects, socio-economic integration processes, and in some places new laws have enhanced modernization trends in montane and alpine land use that have resulted in outmigration and reduced land use intensity at higher elevations in many Asian mountain ranges, providing the chance of ecosystem recovery.

Introduction

The alpine life zone, covering 3% of the world's land area, is commonly defined as being located above the natural high elevation treeline or extending upslope from a boundary corresponding to the global thermal limit for treelines. Alpine areas, however, are of global significance owing to their controlling hydrological function, in particular regarding the flow of meltwater from glaciers and snowfields to the lowlands. Alpine ecosystems represent some of the few remaining wilderness areas of the globe, and encompass some of the most intriguing habitats both in terms of the human fascination with high mountain landscapes and of alpine biota's special adaptations to the harsh physical environment. At the same time, alpine ecosystems are fragile and less resilient since long periods of time may be needed for recovery from damage or excessive stress.

Alpine ecosystems of Asia extend over vast areas; they occur from the higher latitudes to the tropics. The mountain ranges and plateaus of mainland Asia constitute the largest mass of highlands in the world, including all 66 peaks exceeding 7000 m a.s.l. The core of the Asian mountain system is represented by the vast complex of mountain ranges and plateaus around Tibet (including Pamir, Kunlun and Tien Shan) from where mountains and highlands with alpine life zones extend to S and SE Asia (Hindu Kush, Karakoram, Himalaya, some peaks and high valleys on Borneo, Sumatra, Lombok and New Guinea), W Asia (the Urals, mountains around the Iran Plateau, Trans-Caucasian and Pontic Mountains, some peaks on the Arabian Peninsula), and N and E Asia (Altai, Sayan, Changai, E Siberian and Kamchatkan mountains with the transition from alpine to arctic habitats, some ranges and high valleys in E and S China, Taiwan, Korea, and Japan) (Fig. 1).

Alpine life zones are highly susceptible to global environmental change. As elsewhere on the globe, climatic and land use changes are the major drivers increasingly threatening the integrity of alpine ecosystems in Asia, affecting their capacity to provide goods and services (Fig. 2). Alpine regions everywhere in Asia are showing increasing evidence of climate change impacts on physical and biological systems. High elevation environments are in general considered to be among the most sensitive terrestrial systems to respond to climatic variations (Schickhoff, 2011). Observed changes of glaciers, snow cover, permafrost, hydrological conditions, and of the complex altitudinal zonation of vegetation and fauna indicate distinct vulnerabilities. In view of the goods and services mountains provide to about half of humanity, changes in alpine life zones are giving rise to great concern. In the case of water supply, the key function of mountains for humanity, global warming will cause a decline. This reduction of water resources will affect more than half of Asia's population. More than a billion people in Asia live in watersheds of rivers that have their sources in mountains.

Fig. 1 Spatial distribution of mountains in Asia; mountain ranges with alpine life zones are highlighted. Mountain outlines adapted from Körner C, Jetz W, Paulsen J, Payne D, Rudmann-Maurer K, Spehn EM (2017) A global inventory of mountains for bio-geographical applications. *Alpine Botany* 127: 1–15; Background image from https://dds.cr.usgs.gov/srtm/version2_1/SRTM30/.

With regard to physical systems, current global warming has already left distinct traces in the cryosphere and hydrosphere. It is also a powerful stressor on alpine biota, inducing shifts in phenology, species distributions, and community structure as well as other ecosystem changes. Alpine environments in Asian countries are also significantly affected by changes in land use patterns caused by widespread socio-economic change. This chapter reviews the most current knowledge with respect to impacts of climatic and land use changes on alpine life zones of Asia.

Climate Change-Induced Effects in Alpine Life Zones of Asia

Climatic Changes

Global warming reached approximately 1 °C above pre-industrial values in 2017. The high latitudes of the Northern Hemisphere, in particular the northern Asian sector, show the largest increase in mean temperatures (Hoegh-Guldberg et al., 2018). Here, polar amplification leads to warming rates of more than 2 °C per 50 years. Warming trends and increasing temperature extremes have been observed across most of Asia over the past century (Hijioka et al., 2014). Warming trends have been particularly strong in the cold season (November–March). Since the middle of the 20th century, numbers of cold days and nights have generally decreased, whereas numbers of warm days and nights as well as heat wave frequencies have increased (Hijioka et al., 2014). Across Asia, the strongest extreme warming events are projected to occur in western and Central Asia (Hoegh-Guldberg et al., 2018).

Fig. 2 Ladakhi pastoralists let their goats and sheep graze at Lake Tso Moriri (4522 m); the integrity of alpine ecosystems in Asia is threatened by climatic changes and land use changes. Photo © Udo Schickhoff, September 23, 2018.

Temperature trends in most regions of Asian mountain systems substantially exceed the global mean trend since 1880, albeit with distinct patterns of spatial and seasonal differentiations, in particular in terms of vertical gradients. A general phenomenon, prevalent over most of Asian mountain regions, is the amplification of warming rates with increasing elevation, attributed mainly to changes in albedo and downward thermal radiation (Hasson et al., 2016). The amplification of warming with elevation will increase with higher greenhouse gas emission scenarios, subjecting alpine life zones of Asia to more extreme changes in habitat conditions than those of lower elevations (Schickhoff et al., 2016a).

Impacts on Physical Systems

Climate warming causes cascading effects on alpine physical systems, with some of the affected physical processes providing important feedbacks to the climate system. The above-average temperature trends in Asian mountains have inevitable consequences for cryospheric processes, such as substantial changes in snow cover, glaciers, permafrost, and related hydrological processes.

Snow cover is the largest and most important cryosphere component, affecting the global energy budget, water cycle and balance, river discharge regimes, soil moisture, vegetation, and water supply to diverse human activities, including irrigation-agriculture, hydroelectricity generation, industries, tourism, etc. The snow-covered area (SCA) in Asian mountains has significantly declined since the 1960s. The Hindu Kush Himalaya (HKH) and Tibetan regions show declines in snow accumulation rates (Bolch et al., 2019). However, westerly-dominated basins (Indus basin, NW Himalaya) show increases in winter SCA. In the Siberian region including Kamchatka, as well as in the Pamir, Alay, and Altai, the SCA has declined significantly over recent decades, while the Tien Shan and Kunlun show mixed trends (cf. Bormann et al., 2018). The trends of SCA are related to trends in snow cover duration (SCD), which has decreased in the HKH region, Tien Shan, Kunlun, Altai, and Kamchatka by up to 30 days per decade between 1982 and 2013 (Chen et al., 2016).

The mass balance of glaciers in Asia is negative in recent decades (Fig. 3), with some exceptions in the Karakoram, Pamir, western Kunlun, and Altun Shan. The average glacier area loss in the entire extended HKH region was estimated at 0.35% per year between 1970 and 2000; the rate increased to 0.42% per year between 2000 and 2010 (Bolch et al., 2019). Simultaneously, the glacier mass balance rate has increased from -0.26 (m w.e.⁻¹) (1970–2000) to -0.37 (m w.e.⁻¹) in 2000–10, with some regional variations and anomalies. There is a strong E-W gradient of glacier retreat, with average glacier area change rates of -0.81% a⁻¹ in the eastern Himalaya decreasing to -0.37 and -0.34% per year in the central and western Himalaya between 2000 and 2010. In contrast, glacier area changes in the Karakoram show a divergent pattern known as the “Karakoram anomaly.” Non-surge-type glaciers were relatively stable and surge-type glaciers showed large increases as well as decreases over the past decade. Accordingly, most Karakoram glaciers had a positive mass balance in recent decades.

Glacier terminus recession rates have been assessed to be highest in the eastern Himalaya, while a considerably lower glacier recession is observed in the central and western Himalaya, and partially a surging/advancement in the Karakoram (Azam et al., 2018). Recently, recession rates of large glaciers in the central and western Himalaya (Gangotri (Fig. 4); Milam; Bara Shigri) slowed, while glaciers of the NW Himalaya showed very low change rates or were relatively stable (Schmidt and Nüsser, 2012; Mal et al., 2019). Glacier recession has fragmented larger glaciers into smaller ones, resulting in a distinct increase in number and area of

Fig. 3 The margins of Himalayan glaciers are retreating at a fast rate, resulting in the recent formation of meltwater lakes as in the former snout area of Gangapurna glacier (3550 m), Nepal, which create a potential danger from glacial lake outburst floods. Photo © Udo Schickhoff, September 23, 2013.

Fig. 4 Reductions in the area and volume of large glaciers in the Himalaya like the Gangotri glacier (4050 m) will adversely affect the seasonal water supply of a large human population in the lowlands. Photo © Udo Schickhoff, May 6, 2007.

glacial lakes (fed by glacier meltwater; cf. Fig. 3) in recent decades (Krause et al., 2019). The average glacier area loss rate on the Tibetan plateau was slightly lower than in the Himalaya in recent decades, whereas the area shrinkage of glaciers in the Tien Shan, the Caucasus, the Urals, the Altai, and in Siberian mountains including Kamchatka has been considerably higher. Many glaciers in the Chinese part of the Tien Shan and in the Pamir Alay have disappeared.

Permafrost is another important component of the cryosphere, significantly influencing energy balance, terrain stability-related geophysical hazards, ground and subsurface hydrology, river sedimentation, infrastructure, etc. Permafrost degradation contributes to mountain slope destabilization and increased mass-movements and related hazards. Local studies on the Himalayan south slope

suggest widespread permafrost degradation and the rise of the lower limits of permafrost by several hundreds of meters since the 1970s (Fukui et al., 2007). Significant thermal degradation of permafrost has occurred on the Tibetan plateau, in Siberian and Mongolian high mountains and the Tien Shan. Climate change and anthropogenic activities, especially hydropower projects and irrigation, have significantly affected the hydrology in Asian mountains (river discharge, hydrological budgets) during the past century. River runoff in Central and South Asian river basins has decreased up to 30% in recent decades (Scott et al., 2019).

Biotic Responses

Alpine life zones of Asia are being subjected to some of the highest levels of warming globally. Respective biotic responses are increasingly observed, although our understanding of alpine Asian ecosystems remains profoundly deficient (Schickhoff et al., 2016a). Since many plants adjust sequences of phenological events to the rise in temperatures and to the advance in the timing of snowmelt, phenological shifts are considered to be sensitive indications of the response to climate warming. In general, species responses to climate change are driven by their capacity to persist in situ by altering fitness-related traits through phenotypic plasticity or genetic adaptation to novel stresses. However, plants at higher elevations have a low capacity to persist in situ since traits such as slow growth or dwarfism are genotypically determined, and phenotypic plasticity is constrained under harsh climatic conditions. A greater potential for high-elevation species to survive rapid anthropogenic climate change lies in distributional shifts to track preferred bioclimatic conditions. Predicted changes include the gradual transformation of species composition and community structure of resident communities, in particular in the alpine and nival zones. The magnitude and rate of climate change, as well as induced alterations of abiotic and biotic site conditions, will out-strip the adaptive capacity of many species, causing increased extinction risks and loss of biodiversity.

A recent assessment based on satellite-derived NDVI datasets indicates that the length of the growing season in the HKH has increased by 4.25 days per decade over the last five decades, in line with an overall greening trend in NDVI magnitude and an earlier green-up in most parts of the HKH region (Krishnan et al., 2019). Respective observations of shifts in species-specific phenological patterns indicate large-scale changes. Several *Rhododendron* and *Roscoea* species are currently flowering 3–4 weeks earlier than in previous decades (Xu et al., 2009). Telwala et al. (2013) provided evidence of warmth-driven elevational range shifts in 87% of 124 studied endemic plant species in alpine Sikkim over the last 150 years. Considering shifts of species' upper elevation limits of up to c. 1000 m, present-day plant assemblages and community structures are markedly different from those of the 19th century. In recent years, long-term research plots have been established within the Himalayan GLORIA (Global Observation Research Initiative in Alpine Environments) network to monitor details of species distribution patterns. The first resampling of plots in the eastern Himalaya (Hengduan Mountains) after 7 years showed that alpine plants on high-elevation summits increased in number of species, in frequency and in diversity, and that even endemic species showed population increases (Salick et al., 2019). Warming-induced upward migration of plants was recently also confirmed in the western Himalaya by Dolezal et al. (2016), who resurveyed outpost populations of subnival plants after ten years and found an extension of plant species elevational ranges of 120–180 m.

Treeline dynamics and elevational shifts in the HKH region mostly result from combined effects of land use change and climate change. Substantial treeline advances or shrub encroachments into alpine meadows in recent decades are mainly due to land use change. Near-natural treelines on north-facing slopes are krummholz treelines which show a rather low responsiveness to climate warming. The strong competitiveness of krummholz species such as *Rhododendron campanulatum* largely prevents the upslope migration of *Betula* and *Abies* spp. and other tree species (Schickhoff et al., 2015, 2016b). Nevertheless, increasing stand density as well as intense tree recruitment within treeline ecotones point to ongoing treeline dynamics (Schwab et al., 2016, 2017; Bürzle et al., 2018), resulting most likely in treeline advances in the medium- and long-term (Fig. 5). Moreover, modeling studies support the concept of climate change-induced upslope migration of treeline species (Bobrowski et al., 2017; Chhetri et al., 2018). Recent dendroecological studies at HKH treelines indicate a strong sensitivity of tree growth to pre-monsoon temperature and humidity conditions; moisture supply in the dry pre-monsoon season may become an effective control of future treeline dynamics (Schwab et al., 2018; Sigdel et al., 2018).

Recently deglaciated terrain represents another highly dynamic alpine habitat (Fig. 6). The surface area of deglaciated glacier forelands has been increasing considerably due to the ongoing recession of the vast majority of HKH glacial margins. Vegetation successions on glacier forelands have not been addressed in great detail so far. Some preliminary studies have been done on the colonization of glacier forelands by pioneer species (e.g., Mieke, 2015). Similar trends of climate change-induced biotic responses, summarized above for the HKH alpine regions, prevail in other Asian mountain systems and their alpine life zones. Recent positive trends in vegetation growth and productivity, shifts of phenological dates and of the upper limit of species distributions are widespread across Asian mountain ranges.

Effects of Land Use Changes in Alpine Life Zones of Asia

The mountains and highlands of Asia have been subjected to anthropogenic landscape transformation for millennia. Over many generations, mountain dwellers have developed sophisticated, complex resource utilization strategies for their sustenance, including a wide variety of farming and pastoral practices. Initially, mountain nomadism evolved as a strategy to sustain mountain-related livelihoods, often complementing or replacing subsistence hunting and gathering. After the establishment of permanent settlements and village lands, the combination of crop-farming and livestock-keeping evolved as the dominant basis of high mountain

Fig. 5 Himalayan fir (*Abies spectabilis*) sapling found at 4200 m, 100–150 m above the current treeline in Rolwaling Himal, Nepal, reflecting ongoing treeline dynamics. Photo © Udo Schickhoff, August 20, 2013.

agriculture. Pastoral practices in alpine life zones have been increasingly integrated into more complex land use systems including *Alpwirtschaft* (combined or mixed mountain agriculture) and transhumance. In Asian mountains, however, nomadic pastoralism is still found in Siberia and Mongolia, in the Altai, Tien Shan, Pamir, parts of Tibet, the HKH region and in the Zagros. Developing sophisticated practices of combined mountain agriculture involved the clearance of mountain forests which have been increasingly converted to croplands. However, as long as mountain regions remained sparsely settled, human impacts on alpine life zones were negligible for many generations, and remote mountain ranges remained relatively undisturbed. In previous centuries, mountains provided a degree of isolation from the outside world for their permanent inhabitants and were often characterized by distinct inaccessibility resulting in more or less independent subsistence economies with limited trade and exchange relations with the plains or other mountain regions (Schickhoff, 2011).

In the past 200 years, the human populations of many Asian mountain ranges increased markedly, as did the intensification of land use. These changes accompanied the arrival of European colonialism in major mountain ranges. For instance, rapid landscape transformations in the Himalaya, i.e., large-scale deforestation and substantial changes in the distribution of forests and agricultural lands, occurred only after the British annexation of these regions in the 19th century. During the 20th century, the less-developed regions of the Asian highlands experienced high population growth, poverty, lack of economic opportunities, increased land use pressure, and increased integration into the economy of the lowlands. The primary sector had still been growing in importance, and local mountain farmers were often forced to intensify land use in response to internal (population growth) and external (lowland markets) drivers. Most of alpine Asia was subjected to increased pressure on grazing lands that adversely affected highland integrity and biodiversity (Fig. 7). Even the most distant and remote mountain regions were influenced by effects of globalization. Mountains in general have been affected by far-reaching socio-economic transformation processes, notably in the second half of the 20th century. In developed mountain regions (Japan, Taiwan, parts of China and Russia), these transformations have eventually led to the gradual abandonment of traditional land use. These changes took place concurrently with new types of exploitation of high mountain environments, such as tourism, mining, power generation or industrial-scale farming in favorable areas. However, the replacement of farming and herding by tourism is still confined to a few mountain ranges.

Recently, globalization effects and socio-economic integration into the larger world have brought modernization trends in mountain agriculture. Mountain farmers seek to improve their livelihood by combining alternative farming systems (e.g., agroforestry, cash crops), non-agrarian income (e.g., tourism), and migrant labor remittances, while taking full advantage of well-established access to lowland markets, provided by the newly developed road systems. Increasingly, mountain people are moving from remote locations to urban centers. This trend began in the late 20th century. Highland-lowland migration serves to alleviate population pressure on alpine ecosystems, and leads to a reduced land use intensity there. Reduced human pressure may allow ecosystem and biodiversity recovery of previously over-used alpine grazing lands. It also facilitates the introduction of new forms of land tenure, for instance the establishment of national parks and other protected areas whose number has considerably increased in recent decades.

In the vast HKH region, pastoral strategies are still critically important for sustaining livelihoods of a large human population (Kreutzmann, 2012). However, as elsewhere, alpine pastoralism is highly vulnerable to outside forces, such as social, economic and cultural changes. These changes have resulted in a significant decrease in highland livestock grazing. Labor out-migration is the most important driver of reduced alpine land use intensity. In Nepal, for instance, the migrant population is steadily increasing. Almost 500,000 workers left Nepal in 2014 to work in India and elsewhere, consequently, remittances (i.e., money sent home by Nepalese working abroad) now constitute more than 30% of the country's gross domestic product (Siddiqui et al., 2019). Animal husbandry in the HKH region has seen a general decline. Likewise, land abandonment and the decrease of traditional agricultural practices due to labor shortages are apparently more pronounced at higher elevations. Whereas the decline in grazing intensity in the Himalaya mainly results from modified strategies adopted by pastoralists, reduced high-elevation pasture utilization on the Tibetan Plateau as

Fig. 7 Livestock grazing is the predominant land use at higher elevations in Central Asia, large highland tracts have thus been subjected to overgrazing, Altai Mountains, western Mongolia. Photo © Udo Schickhoff, September 10, 2005.

well as in high mountain ranges of E and S China has been driven by Chinese government programs aimed at the transformation of the pastoral sector. These programs include human resettlement schemes and the forcing of nomadic peoples to live in permanent settlements, with the aim of modernization and the reduction of grazing pressure and ecological degradation. In recent decades, overgrazing was a major stressor on alpine ecosystems. Indeed, poor livestock management practices have resulted in the degradation of alpine grazinglands across the entire HKH region, in particular in drier parts and on the Tibetan Plateau (e.g., Baranova et al., 2016). The current overhaul of alpine pastoralism practices provides hope that pasturelands will no longer be grazed beyond their carrying capacity, and that formerly degraded rangelands will recover.

Since time immemorial, pastoralism has dominated alpine land use in the Pamir, Tien Shan, and Altai, playing a crucial role in Central Asian economies, societies, and cultures. In the former Soviet Central Asian Republics, pastoral traditions and strategies have undergone tremendous changes in the course of the 20th century, driven by strong external interventions. The first decades of the Soviet era were characterized by forced sedentarization and collectivization campaigns, resulting in intensification of pastoral land use and its integration into socialist agro-industrial production. The disintegration of the Soviet Union in 1991 and the subsequent political and economic upheavals forced regional inhabitants to develop different pastoral strategies, based on private ownership of livestock, subsistence farming, and little state interference in land use practices. Deindustrialization, the initial decline of national economies, and the disappearance of social safety net have led, among other things, to an increased dependency on grazingland resources. After three decades of post-Soviet transformation, an increased scope and diversity of pasture-related socio-ecological challenges can be observed. These include conflicts about access to pasture lands, utilization rivalries, insufficient management practices, and degradation processes (Borchardt et al., 2011; Dörre and Borchardt, 2012). These conflicts have arisen in spite of state efforts to decentralize governance and to establish community-based pasture management. The spatial pattern of pasture degradation has changed in recent decades. Grazing intensity on remote high elevation summer pastures has declined because farmers have abandoned the practice of seasonal livestock migration (Fig. 8). In contrast to this, winter pastures, located close to settlements, have been subjected to more intense grazing pressure with adverse effects on vegetation, plant functional traits, and soils such as lower species richness and diversity, lower biomass, decreased plant height and specific leaf area, lower organic matter content, and higher soil pH values (e.g., Hoppe et al., 2016).

The history of mobile pastoralists' land use strategies and livelihoods in alpine zones of Mongolian mountain ranges in the 20th century has many similarities to the former Soviet Central Asian Republics. The revival of pastoral nomadism in the early 1990s resulted in rapidly growing livestock populations, shifts in herd composition, and widespread degradation of rangelands, also at higher elevations. The ongoing establishment of community-based rangeland management—over 2000 formally organized herder groups formed since 1999—is a promising institutional innovation which should support the implementation of strategies leading to sustainable pastoral land use. Land use patterns and livelihoods of pastoralists in Russian mountain ranges (Siberia, the Urals) have been affected by the implementation of post-socialist land use policy in a similarly fundamental way, subjecting herders to socio-ecological challenges such as unequal allocation of grazingland and localized high grazing pressure.

Fig. 8 Grazing intensity on remote summer pastures in the Tien Shan has been decreasing recently due to declining seasonal livestock migration, Suusamyr valley, Kyrgyzstan. Photo © Udo Schickhoff, September 26, 2004.

In the Caucasus, post-socialist land reforms have resulted in outmigration, land abandonment, and increasing use of the land for recreational activities. By contrast, alpine ecosystems of Iran are increasingly threatened by increased grazing impact, even in protected areas. Overgrazing has also caused severe pasture degradation in the Pontic Mountains. Land use impacts on alpine life zones in New Guinea are considered to be relatively low, with the exception of some mining impacts on Mt. Jaya and recently developing ecotourism on Mt. Wilhelm. Increasingly adverse tourism impacts on the alpine environment are also to be observed on Mt. Kinabalu, Borneo.

Conclusions

This review illustrates the fundamental changes happening in the alpine ecosystems of Asia. Across most of Asia, snow cover is declining, glaciers are thinning, losing mass, and their margins are retreating. Permafrost is also degrading. Increasing cryospheric changes in coming decades will add to natural hazard risks, and affect seasonal water supply in Asian river systems, with potentially severe implications for agriculture, hydropower generation, and local water resource availability. This may lead to conflicts over water resources and threaten livelihoods and food security of millions of lowland people, in particular in South and East Asia. Biotic responses to climate change such as phenological shifts, changing species distributions, migration of invasive species, and changes in primary production will modify species compositions of communities and thus the structure and functioning of alpine ecosystems, threatening the provision of ecosystem services. Pastoralism is still widespread in alpine Asia, sustaining the livelihoods of a large human population. The recent trend of reduced land use intensity in many mountain ranges provides the chance for ecosystem recovery. However, establishing the kind of land use practices in high mountain regions that would safeguard human livelihoods while simultaneously maintaining ecological sustainability remains a considerable task. Such changes need to be embedded in the major challenge of mitigating negative effects of drivers of environmental and socioeconomic change in alpine Asia.

Abstract

The New Guinea alpine zone above 3750 m elevation is the highest, largest and wettest such region on any tropical island. The modern alpine consists of islands of habitat spanning 1400 km with considerable variations in biodiversity between the individual mountain areas. During the Pleistocene glacial periods, a zone above 3400 m was affected by glaciation and alpine habitat was greatly expanded. With post-glacial warming the alpine contracted and shrublands colonized the lower alpine. Current climate warming has nearly removed the nival zone but tree lines have not yet noticeably advanced to higher elevations. Successional changes to mature, waterlogged, soils have been observed. The alpine is threatened by increased warming and potential invasion by emergent shrubs but is unlikely to disappear, provided that wet conditions continue to prevail.

Opening out of the tree line in the past is associated with fire that may reflect visits by people for hunting. Evidence for fire spans several millennia in some areas but is quite recent on other mountains or absent on more remote peaks. Some alpine mammals and birds have disappeared or suffered local extinctions. Changing cultural use of high elevations suggests that previously disturbed habitats may be recovering in some areas.

With few exceptions, land management depends on local populations; widespread fires during El Niño induced dry phases point to continuing human impacts linked to drought events. The alpine has not been greatly affected by modern development although a large mine on Mt. Jaya influences subalpine usage over a large area. Tourism is very minor and unlikely to expand while political problems affect both PNG and Papua province and infrastructure remains rudimentary. However, locally managed tourism on Mt. Wilhelm provides a good model for future development.

The Alpine across New Guinea

Alpine habitats in the great equatorial island of New Guinea occur above 3600–4100 m and cover approximately 3300 km² at present.

The alpine zone in New Guinea has been defined as: “a treeless zone bordering a transitional subalpine zone and along its higher altitudinal border limited by the last vascular plants” (van Royen, 1979, p. 22). However plants occur up to the highest points available and it is unlikely that a true limit to growth is reached. The tree line varies, being highest on limestone at up to 4050 m and lower on the shaded and waterlogged parts of volcanic and metamorphic mountains at 3650 m a.s.l. In most areas however, the natural tree line has been greatly disturbed, and open grasslands are extensive to below 3000 m a.s.l. (Fig. 1).

Some of these lower grasslands are regarded as subalpine as they support shrubs and tree ferns that are absent from the alpine. The subalpine forest is low (10–15 m) and variable, transitioning from taller complex forest (upper montane forest) around 2800–3000 m a.s.l. On some mountains it is reduced to scattered trees or small forest patches surrounded by grassland.

The New Guinea alpine is an example of islands within an island-numerous young isolated and fluctuating habitats with island-like characteristics of habitat, local endemism and active species radiations (Green and Stein, 2015). As such it is a remarkable laboratory for studying evolution and differential adaptation to climate change in conditions of relatively low past human impact. This article considers causes of change to the alpine vegetation but in doing so it emphasizes the paucity of knowledge currently available.

Successional Change

Mapping alpine tundra-like habitats as fixed vegetational units ignores the fact that these pioneer communities are usually developing into more complex communities with deeper and more productive soils. At high latitudes like the Arctic or sub-Antarctic, such successional changes are very slow due to extremely low winter temperatures and very short growing seasons when there is sufficient radiation for plant growth. Hence Arctic plant community boundaries may be fairly stable on timescales of decades to centuries. By contrast, at high elevations in the tropics, despite low mean daily temperatures, there is abundant radiation throughout

Fig. 1 *Poa erecta* tussock grassland and infilled glacial basins on the summit plateau of Mt. Albert Edward. Photo: M. Prebble (2008).

the year and plants can grow in microhabitats that may be quite warm for a few hours each day. Here successional change can be relatively rapid.

The potential rate of change can be estimated by comparing alpine grassland-low shrubland on well-developed soils with very open dwarf shrublands on fresh moraines. The young moraines have been exposed by ice retreat within the last century so the succession to open dwarf shrubland has presumably occurred within several decades. Current snow and ice retreat (Prentice et al., 2011) exposes fresh rock and till surfaces to a rapid succession by fungi, algae, lichens, bryophytes and vascular plants.

Similarly ponds and tarns are being invaded by a range of mosses, sedges and herbs to form fens. Open mosslands on flooded pans develop towards herbfields and cushion bog. The complex development of lichen, moss and liverwort associations on rock and scree surfaces have not been studied in New Guinea. Mangel (1993) describes cliff and scree cryptogam communities that develop rapidly in the misty humid environment. Fig. 2. The moss and lichen mats trap humic soils which are then invaded by grasses and small shrubs.

Fig. 2 Lichens and mosses colonizing a granodiorite slab at 4400 m, Mt. Wilhelm. The shrub is *Vaccinium amblyandrum*. Photo: G. Hope (2010).

Fig. 3 Ice algae communities on the now defunct Meren Glacier, 4420 m, Mt. Jaya. Photo: G. Hope (1971).

The loss of ice cover has caused specialized snow algae communities to disappear. These communities have only been described from Mt. Jaya (Kol and Peterson, 1976) and they consist of colonies of six species of green algae and a blue-green alga, *Nostoc fuscescens* var. *carstenszis*. The colonies of algae increase the absorption of sunlight and lead to localized melting and the development of blue englacial ponds ranging up to 10 m or so in diameter. Fig. 3 shows the ablation (melting) zone of the Meren Glacier in 1970 with well-developed ponds. These have now disappeared with the melting of the glacier.

Invasive Species

Invasive plant species are not well known from the New Guinean alpine and currently play little part in the alpine vegetation. Native shrubs from the subalpine such as the tall daisy, *Papuacalia versteegii* (Asteraceae), have been seen growing vegetatively in newly exposed till at 4250 m altitude on Mt. Jaya. Other readily dispersed taxa will potentially follow.

Some exotic composite weed species such as thistles and other weeds such as *Anagallis arvensis* invaded the subalpine after the 1998 fires and were still persisting in burnt grasslands on Mt. Giluwe in 2001. Hence these disturbances provide a route for invaders. European bulbs such as *Lilium* and grasses such as *Poa annua* are following track lines upwards on Mt. Wilhelm. Other introduced grasses, composites and *Lantana* are potential threats. Mt. Albert Edward supports a large pig population causing disturbance of large areas due to their seeking roots and worms in grassland. These overturned patches result in local erosion and damage from grass fires. Potential problems could arise from other introduced mammals such as rabbits.

Possible Impacts of Climate Change

The rapidly disappearing ice cover on the New Guinea alpine summits provides the clearest evidence for climate warming in the Asian tropics. Warming has been occurring for at least 110 years and probably since the Little Ice Age ended around 1850 BCE. In Papua province (Indonesia) the four highest areas supported glaciers or ice caps and ice extent is estimated to have been about 42 km² in 1907, mostly on Mt. Jaya (Carstensch). The ice cap on Mt. Trikora disappeared around 1942 (Hope et al., 1973) and on Idenberg and Mt. Mandala (Juliana) in the 1990s. The Carstensch icecaps have reduced to two small areas totaling about 0.6 km² in 2012 and are expected to be gone in the next few years (Prentice and Glidden, 2010; Lavers and Abbott, 2016), Fig. 4. The highest rate of retreat occurred during pronounced El Niño events in 1997–9 and 2008. The less cloudy conditions and lowered snowfall led to accelerated ablation and strongly negative mass balances (Prentice and Hope, 2007).

The warming trend indicated by these reductions in ice cover correlates with a mean temperature increase of 1 °C since 1880. Phenological changes have been noted in species in the alpine zone including flowering at higher elevations. However there are no systematic observations and many changes, such as increasing shrub cover, may be responses to changing disturbance regimes and not climate change. At lower elevations Bourke (2011) has identified significant changes in the ranges of economic plants over the past 30 years that point to temperature increases of 1 °C and lower frequencies of limiting conditions, such as frost.

Fig. 4 Ice retreat on Mt. Jaya. The lighter blue and blue hatching indicates probable ice extent in 1850. Middle blue shows the extent in 1980 and the darkest blue the extent in 2000. Diagram by M.L. Prentice.

Few direct climate observations have been made in the alpine. Two dataloggers were buried at a depth of 10 cm at treeline on Mt. Wilhelm from 2007 to 2010 (**Fig. 5**). No warming trend was observed and the records displayed the least seasonal changes known for any tropical mountains (C. Korner and K. Green, pers. comm.; [Korner, 2012](#)). This may indicate that under moist and foggy conditions relatively little change is occurring at high elevation.

Fig. 5 Data logger site on Bogunaltobokwa Ridge at 3990 m on Mt. Wilhelm. The *Rapanea vaccinioides* trees have been stable for 40 years. Photo: G. Hope (2010).

A good reference climate station exists at the Ertzberg mine site at 3650 m on Mt. Jaya (Prentice and Hope, 2007). The rainfall data at this station identified the large impact of the 97–98 El Niño on the snowline at that time, which rose 100 m but then stabilized before retreating more slowly. This highlights that future climate impacts might follow increased and more severe drought events. These events include low cloud cover and a 30% reduction in rainfall for several months, with runs of weeks between significant rain events. During the El Niño, plants show signs of wilting and surface peats are dry. Mosses and lichens become crisp and may flake off while shallow ponds dry out and the sediments crack. Low humidity combines with low vapor pressure to dessicate plants and soils quickly. The clear skies result in very high levels of UV radiation which may bleach leaves and influence flowering. Since the flora is not adapted to drought, the effects of an El Niño event may be very disruptive, as suggested for Mt. Kinabalu by Kitayama (1996). Exposed ground provides habitat for colonizing herbs and lichens but is subject to frost-heaving and erosion.

Rising temperatures can be expected to result in changing plant altitudinal limits and community changes (Green and Stein, 2015). In the next few centuries there will be a reduction of rocky open habitats in the face of generalized warming which may result in increasing shrub cover and a rise in the tree line as frost-sensitive taxa migrate upwards. Raised CO₂ levels will encourage woody plants to invade grasslands. The evidence for this can be seen by comparing old photos with more recent ones in areas of little human impact. The effect is not marked to date and in many cases fire is maintaining or reducing shrub cover.

The Owen Stanley Range around 8° S in the southeast of New Guinea has a more-seasonal climate with a winter dry season. The ecology there may indicate a possible trajectory for the alpine vegetation in wetter alpine if drought events become more common. Mt. Albert Edward has a widespread low *Poa erectifolia* grassland across the summit plateau and heath areas are restricted to rocky outcrops (Fig. 1).

While paleoecological study (Hope, 2009) shows that the grassland has a very long history, its wide extent is due to fire that has prevented forest from becoming established at the highest limits. The predicted increase in shrubs is being prevented by widespread burning by both intentional fires and lightning-caused ignitions.

Disturbance: Fire, Development, Tourism

As treelines rose across the island when climates warmed after 15,000 year BP, in some areas burning by humans seems to have maintained open areas with alpine vegetation. In fact fire has continued to expand the available habitat for treeless subalpine vegetation throughout the last 9000 years (Hope and Haberle 2005). If major drought events increase in frequency then human ignited, and possibly natural, fires will alter the balance further. Large blanket peat areas (Hope, 2007) may dry out in droughts and are at risk of burning.

Agriculture is not practiced above 2800 m so the main traditional purposes for visiting alpine areas are for hunting (Fig. 6) and to traverse the range crests to reach settlements across the ranges. Animals sought at high elevation include the worm-eating monotreme, *Zaglossus bruijnii*, possums, birds such as the Snow Mountains quail and giant rodents like *Mallomys antap*. Traditionally parties of men would use high elevation huts or rockshelters for a week or two, returning to the village with a proportion of the game, including captured live animals, skins and feathers for ceremonial dress. Large quantities of wood were needed to support these camps and fires often escaped. A small kangaroo of the treeline, *Thylogale christensenii*, became extinct in the Papuan mountains around 3000 year BP (Flannery, 1992) and monotremes such as *Zaglossus* are now absent from the PNG highlands but still to be found in the subalpine of Papua and the Owen Stanley Ranges (Flannery, 1995). The bird of paradise with the highest elevation

Fig. 6 Copper ringtail possum captured in the Prinz Willem Range, Papua. This species has occupied alpine habitat as other fauna has been made extinct. Photo: Bren Weatherstone (1993).

range, *Macgregoria pulchella*, has a similar fragmented distribution that is probably the result of excessive hunting near large montane population centers. On Mt. Wilhelm fronds of an obligate ground fern, *Polystichum (Papuapteris) linearis*, is sought as bride price goods and for decoration.

With the arrival of modern states, alternative transport has reduced the use of tracks in the high country. For example, tracks crossing over Mt. Wilhelm from the upper Chimbu to Kerowagi are rarely used today, as lower elevation roads allow easier travel and old enmities that prevented free passage have relaxed. In a few instances the gradual loss of forest has been reversed. On the Kemabu Plateau north of Mt. Jaya, the vegetation is becoming more shrubby and overgrown while regeneration on stone pavements indicate an easing of the former destructive fire regime that destroyed the soil cover. This inferred reduction in human impact is supported by pollen data from Ijomba swamp which show increasing shrub and tree-fern cover after 2500 years ago when hunting may have lessened (Hope and Haberle 2005; Hope, 2014).

A new road is currently being built that traverses the alpine west of Mt. Trikora at 3800 m and connects the regional center of Wamena with Nduga. This road will likely replace a network of tracks that cross the range. The environment along the road will experience increased impact, but the general use of the high elevation away from the road may be reduced.

Different histories are known from other mountains such as Mt. Scorpio and Mt. Giluwe where grassland is still replacing subalpine forest due to fires lit by hunting parties (Fig. 7).

Some summits, such as Mt. Albert Edward, host radio telephone equipment serviced by helicopter but facilities on some other mountains (Mt. Giluwe, Mt. Ialabu, Mt. Wilhelm) have been abandoned as mobile phone technology expands.

There are exceptions to this scenario of relatively low human impact. The area near the Ertsberg and Grasberg copper-gold mines west of Mt. Jaya are impacted by a large open cut pit and extensive tipping of waste rock up to 4300 m elevation on formerly glaciated terrain. (Fig. 8). Mine spoil has buried the known habitat of an alpine community, *Euphrasia lamii-Tetramolopium distichum* herbfield, that was colonizing limestone screes and fans.

Mine workers from villages to the north now walk several days to and from the mine across the Kemabu Plateau. Mine workers also visit the ice area with consequent litter problems (Utteridge and Edwards, 2009). The mine is enclosed by the Lorentz National Park, a 25,056 km² reserve that extends 150 km from Mt. Jaya to Mt. Trikora across the largest high-elevation area on the island. The Park is not managed to any great extent at present and traditional uses such as hunting are continuing. The Park and many other high elevation areas were affected by widespread fire during the 1997–98 El Niño event.

Tourism to New Guinean mountains is quite minor in comparison with the massive popularity of mountains such as Mt. Kinabalu Malaysia. Numbers may even have reduced as the logistic difficulties and security problems in both Papua and PNG are perceived to have increased. An exception to the absence of tourism is Mt. Wilhelm, at 4509 m the highest mountain in PNG, where local groups are developing ecotourism along the Pindaunde valley, the most popular route to the summit from the road head at 2850 m. Lodges have been built with locally collected funds and official guides are employed. Tracks have been improved, funded from guide fees. Fuel for cooking is brought up to the subalpine and cutting the subalpine forest is discouraged. The area above 2900 m is national land but managed by the agreement of the local landowners. Visitor numbers are still relatively low, at a few hundred per year, but the enterprise provides a possible model for the management of other mountain areas. Gaining an income then provides incentives to maintain the vegetation and wildlife. The concentration on a single valley allows other valleys to remain

Fig. 8 The huge Grasberg mine on Mt. Jaya has removed several km² of alpine habitat, leaving a 1 km deep pit and placing overburden up to 4300 m. It has also disrupted traditional trackways across the mountains. Photomosaic Freeport McMoren (2010).

Fig. 9 Eroding track at 4250 m, Mt. Wilhelm. Photo: B. Pillans (2010).

unvisited because access is much more difficult. Visits are generally of short duration (2–4 days) so far. Track damage and some litter problems can be observed in the alpine but these could be readily fixed if visitation and hence income increase (Fig. 9).

A niche tourism market arises from the status of Mt. Jaya as the highest summit in Oceania leading to a market that caters for mountaineers keen to ascend the peak as one of the “Seven Summits.” Climbing the Carstensz Pyramid is the only one of the Seven Summits which specifically requires technical rock-climbing experience with routes of a difficulty up to 5.8. Expeditions are organized by trekking companies who can handle the visa and travel permit requirements. Groups fly into Sugapa, a small airstrip south of the mountain, and walk for 3 days to reach the alpine area. A popular recent alternative is a direct helicopter charter to the mountain. Benefits (and incentives for conservation) largely evaporate if centralized tourism companies based in towns take over the

activities and tourism management. This has been the tendency in ecotourism and climbing groups on Mt. Trikora and Mt. Jaya where the web largely promotes Jakarta-based firms and local attempts to provide services lose out to better organized and resourced firms with better market access and government connections.

Other mountains are occasionally visited and often publicized by web blogs. These include Mt. Victoria, Mt. Albert Edward, Saruwaged Mts, Mt. Giluwe and Mt. Scorpio in PNG and Mt. Mandala and Mt. Trikora in Papua. Very limited scientific research currently takes place on the New Guinea alpine but occasionally leads to new work on otherwise unvisited mountains such as Mt. Strong (Bishop Museum), Mt. Trikora (LIPI, Wamena) and the Finisterre Range (Lamont).

Discussion

The present status of both management and research on the subalpine and alpine of New Guinea is one of benign neglect. PNG lacks an organized reserve system while Papua has defined conservation areas and management aims but few resources to implement them. In general traditional resource use for the alpine continues unchanged. It seems likely that increasing montane populations and rising temperatures will cause subalpine forest to be cleared and crops such as potato and cabbage to expand to higher altitudes. The indirect effect of this will be to make the alpine more accessible, with risk to wildlife. However traditional use of the alpine has been minor and may now be declining as the population of montane villages becomes more oriented to town life. Over the past 40 years I have found it harder to find knowledgeable guides with the skills to work in the high regions, and many areas seem less visited, despite generally increasing highland populations.

Many isolated mountain areas across the island have never been studied and are rarely visited. Research is at the early stage of collecting and description in most cases. Offsetting this is the increasing maturity of local universities and research institutions, whose students and staff are undertaking research projects that may include alpine projects. In the longer term the magnificent landscapes will draw visitors and necessitate more targeted management.

Abstract

Alpine ecosystems in the Pacific Islands are isolated and unique, characterized by high levels of endemism. Only Hawai'i and New Zealand have elevations high enough to contain substantial alpine climates, and about 11% of the land area of both island groups is located above treeline. Both of these volcanically active archipelagos are characterized by complex topography, with peaks over 3700 m. These alpine ecosystems have significant cultural, social, and economic value; however, they are threatened by invasion of exotic species, climate change, and human impacts. Nonnative ungulates reduce native shrubland and grassland cover, and threaten populations of endangered birds. Exotic plants alter water yields and increase fire risk, and increased recreational visitation to these remote areas facilitates the introduction of exotic plant seeds, pests, and pathogens. Both New Zealand and Hawai'i have experienced strong warming at higher elevations, and future projections indicate that these robust warming trends will continue. Glacial retreat has been noted in the Southern Alps, with 34% ice volume lost since 1977, and New Zealand may lose 88% of its ice volume by 2100. Snowfall on Hawai'i's mountain peaks is projected to almost entirely disappear by 2100. Changes are occurring rapidly, and additional monitoring and research are needed to conserve these uniquely sensitive, remote regions.

Introduction

Alpine ecosystems occur above the altitudinal limit of forests, known as the treeline. Complex mountainous topography leads to climates that change rapidly with elevation over short distances, resulting in steep gradients in vegetation and hydrology. Alpine ecosystems are often characterized as biodiversity “hotspots” and by high levels of endemism due to the isolation of species at high elevations (Beniston, 2003). On oceanic islands, geographic isolation has further contributed to the endemism found in these rare, unique alpine environments, and they are subject to markedly different oceanic-influenced climates than continental areas (Harter et al., 2015). Treelines here are also found at lower elevations than mainland treelines and are likely controlled by regional climatic factors (Irl et al., 2016).

Many studies have suggested that alpine ecosystems are among the most sensitive to climatic changes (e.g., Diaz et al., 2003), and growing evidence indicates that high mountain environments are warming faster than lower elevation areas (Pepin et al., 2015). This enhanced warming with elevation can accelerate the rate of change in mountain ecosystems, requiring species to respond by acclimating, adapting, moving, or facing extinction (Corlett and Westcott, 2013). For many alpine species, warming is expected to cause substantial range losses (Dullinger et al., 2012), and evidence indicates that many plant species will not be able to keep up with rapid changes in climate expected in the 21st century (Corlett and Westcott, 2013). For islands, the threat of climate change is even greater as native species are often poor competitors against introduced species, have limited potential to migrate because of the surrounding ocean, and for species at the highest elevations, migrating further upward is not possible (Harter et al., 2015). Climate change impacts on high islands can therefore result in a disproportionately high potential for global biodiversity loss.

Changes in high elevation ecosystems and the resources they provide can also be driven by numerous other factors, including overgrazing by livestock, invasion by nonnative species, land use change, and environmental stress from human activities (Beniston, 2003). Islands in particular are more vulnerable to anthropogenic impacts due to their limited land areas (Kier et al., 2009). Alpine ecosystems are susceptible to landslides, soil erosion, and loss of biodiversity and endemic species. Changes to these ecosystems impact the landscape, hydrological regimes, and water resources, with downstream impacts to the lowland areas and a wide range of socioeconomic consequences (Diaz et al., 2003).

In the Pacific Ocean, islands range in size from small low-lying coral atolls at sea level to large islands with volcanic peaks at 4200 m. Alpine ecosystems in the Pacific Islands are primarily concentrated in Hawai'i, New Zealand (Aotearoa), and Papua New Guinea. It should be noted, however, that Tahiti in French Polynesia (maximum elevation 2241 m) and Vanuatu (1879 m) contain some subalpine shrublands with low scrubby and herbaceous vegetation above the cloud forest on the highest peaks (Leuschner, 1996; Meyer et al., 2010). The Solomon Islands (2335 m) are forested to the summits with some local *Sphagnum* moss alpine bogs (Leuschner, 1996). Australia also contains approximately 11,500 km² of alpine and subalpine habitat concentrated mainly in the southeast of the continent and the island of Tasmania (Williams et al., 2008). For more information on alpine ecosystems of Australia, please refer to McDougall and Walsh (2007), Slatyer (2010), and Kirkpatrick (1983). This article focuses on characterizing current changes in alpine environments of Hawai'i and New Zealand. The section "High Elevation Ecosystems in Pacific Islands" describes the vegetation and climate of these ecosystems, while the "Current Changes" section describes current changes in these regions, followed by a "Concluding Remarks" section.

High Elevation Ecosystems in Pacific Islands

Geologic Setting

New Zealand's approximately 260,000 km² of land area today represents only 5% of a much larger, submerged continent known as Zealandia. New Zealand (Fig. 1) is a mountainous country located between 34° and 47°S latitude and 166° to 179°E longitude. Around 11% of the total land area is above the treeline (Halloy and Mark, 2003). The highest point above sea level is Aoraki/Mount Cook (3754 m) located in the Southern Alps on the South Island, and another 222 named peaks have elevations > 2300 m (Campbell et al., 2012). Alpine areas on the North Island are limited to a few peaks above treeline, and only the active stratovolcano Mount Ruapehu (2752 m) supports glaciers (Chinn, 2001). The Southern Alps were created by the collision of the Pacific and Australian plates, starting about 5 million years ago, and were extensively glaciated around 20,000 years ago during the Last Glacial Maximum. The Alpine Fault spans the length of the Southern Alps from north to south and regularly produces large earthquakes, which, along with erosion and tectonic activity, have shaped the unique mountain topography found today (Campbell et al., 2012). Active volcanic areas are confined to six areas: five in the North Island and one offshore to the northeast. From a geophysical standpoint, New Zealand possesses characteristics of both islands and continents, so it is not surprising that its remarkable biodiversity occurred as a result of both dispersal from nearby land masses and evolution from ancestors of Zealandia (Wallis and Trewick, 2009).

The Hawaiian archipelago lies in the center of the Pacific plate between 18° and 23°N latitude and 160° and 154°W longitude and was formed by volcanic activity as the plate slowly moved over a hotspot (Macdonald et al., 1983). The islands extend over 2400 km from Hawai'i Island in the southeast to Kure Atoll in the northwest, ranging in age from 0.5 to 28 million years. Hawai'i is nearly 4000 km from the nearest continent, and is one of the most isolated major archipelagos in the world. Eight main islands (Fig. 2) have a land area of 16,637 km² (Juvik and Juvik, 1998), of which Hawai'i Island is the largest and contains three of the four highest peaks: Mauna Kea (4205 m), Mauna Loa (4169 m), and Hualālai (2521 m). Mauna Loa and Hualālai are active shield volcanoes; Mauna Kea is a dormant shield volcano (Juvik and Juvik, 1998). To the west of Hawai'i Island is the island of Maui, whose tallest peak, Haleakalā (3055 m), is also an active shield volcano (Juvik and Juvik, 1998). These four peaks are home to all of Hawai'i's alpine and subalpine vegetation, and similar to New Zealand, Hawai'i's tropical alpine and subalpine regions comprise ~11% of the land area.

Climatology

The climates of Pacific Island highlands are subject to strong influences from the surrounding ocean, and precipitation patterns are predominantly driven by orographic processes. Interdecadal and decadal climate variability are driven by large-scale modes of variability, including the El Niño-Southern Oscillation (ENSO) (Frazier et al., 2018; Sturman and Wanner, 2001). New Zealand experiences westerly winds in the mid-latitudes, while Hawai'i is subject to northeast trade winds in the tropics, and the perpendicular orientation of the mountains to the prevailing moisture-laden winds results in extremely wet windward areas (over 10,000 mm year⁻¹ on both the western slopes in New Zealand and the eastern slopes in Hawai'i; Giambelluca et al., 2013; Hendriks et al., 2012). Extreme gradients characterize both archipelagos, with a stark contrast in the rain shadow of the dry leeward areas where precipitation can be as little as 500 mm year⁻¹ in New Zealand and ~200 mm year⁻¹ in Hawai'i (Giambelluca et al., 2013; Tait et al., 2006). Mean annual temperatures range from -6.9 to 8.2°C and from 3.6 to 10°C in alpine areas of New Zealand and Hawai'i, respectively (LENZ, 2010; Giambelluca et al., 2014). In New Zealand, cold fronts originating along the eastern side of the mountain range can cause sudden drops in temperature and increases in humidity, with damaging winds (Sturman and Wanner, 2001). Wind speeds exceeding 160 km h⁻¹ have been recorded at the higher elevations in New Zealand. New Zealand experiences extensive seasonal snow cover (Hendriks et al., 2012), while in Hawai'i, snow occasionally falls on the highest mountains, although no direct measurements of snow are currently recorded (Zhang et al., 2017). In Hawai'i, high elevation areas have some of the lowest evapotranspiration and rainfall rates, the lowest cloud frequency and relative humidity, and the highest solar radiation (Giambelluca et al., 2014). These climate patterns are largely driven by the presence of an atmospheric inversion layer around 2150 m, known as the Trade Wind Inversion (TWI), which caps cloud growth and produces extremely dry, sunny conditions above (Longman et al., 2015a). This sharp change in moisture availability, combined with extreme El Niño-induced drought events, is thought to drive the position of the treeline (Crausbay et al., 2014).

Fig. 1 Elevation zone map of New Zealand showing land above the approximate treeline elevation. Some individual summits and glaciers discussed in the text are labeled.

Ecological Zones and Plant Communities

Treelines in New Zealand occur within similar thermal ranges as in other sites worldwide (although at lower elevations; Cieraad et al., 2014). The high altitude tree limit in New Zealand's alpine regions is dominated by two species of evergreen *Nothofagus* trees ranging from ~1000 m in the southern part of the Southern Alps to ~1400 m on the North Island (Wardle, 2008). Above the treeline, the vegetation of the high mountains (Fig. 3) consists of a lower alpine zone dominated by shrubs and tall tussock grasslands and a high alpine zone dominated by dwarfed plant communities and grasslands (Mark et al., 2000). There are no native mammalian herbivores in this region. The snow tussock lands (*Chionochloa* spp.) in the southeastern South Island are known to intercept large amounts of fog that contribute substantially to the water yield from these uplands (Mark et al., 2013). Above the high alpine zone lies the permanent snowline, which is the lower limit of the nival zone (Mark et al., 2000). Areas of permanent snow are extensive along the central Southern Alps and in the southern part of the range (Fig. 1). Over 3000 glaciers have been identified, and as a result of the strong precipitation gradient they range in elevation from ~1600 m in elevation in the west to ~2500 m in the east (Chinn, 2001). Terminal alpine lakes are frequently present at the base of glaciers (Fig. 3A). Permafrost is found at the higher elevations in the central part of the range (Sattler et al., 2016).

Fig. 2 Elevation zone map of the main Hawaiian Islands showing land above the approximate treeline elevations. Some individual summits discussed in the text are labeled.

In Hawai'i, between ~2000 and 3000 m are subalpine forests, woodlands, and shrublands. The treeline of Mauna Kea is typically defined as the upper extent of the māmane (*Sophora chrysophylla*) woodland and is located ~2900 m above sea level (Gerrish, 2013; Leuschner, 1996). The treelines of Mauna Loa and Haleakalā are at least 450 m lower than on Mauna Kea, which may be due to soil-dependent factors (Leuschner, 1996). Along parts of the northeastern slope of Haleakalā, the treeline occurs around 2100 m and is delineated by plantations of conifers that were introduced in the early 1900s. In other areas, treeline elevation varies and is made up of native subalpine cloud forest dominated by 'ōhi'a (*Metrosideros polymorpha*), which gives way to alpine shrublands, herbs, and tussock grasslands that form a fog-drip community of alpine scrub (Crausbay and Hotchkiss, 2010). Alpine desert conditions exist on Maui and Hawai'i Island above ~3000 m. These are dry and semibarren, with dwarf native shrubs dominated by pūkiawe (*Styphelia tameiameia*), 'ōhelo (*Vaccinium reticulatum*), 'āhinahina or Hawai'i silversword (*Argyroxiphium sandwicense*), and na'ena'e (*Dubautia* species). At the summits, eolian deserts (also called stone deserts, Fig. 3C) are populated with grasses, mosses, and lichens (Gerrish, 2013; Juvik and Juvik, 1998).

Mauna Kea was home to a 70 km² ice cap until 15,000 years ago, which left conspicuous, preserved moraines (Anslow et al., 2010). Despite mean annual temperatures well above freezing, perennial ice is present as permafrost inside two cinder cones on Mauna Kea and two lava tube ice caves on Mauna Loa (Schörghofer et al., 2018). Hawai'i's only alpine lake, Lake Waiau (3970 m) (Fig. 3D), is found in the Pu'u Waiau cinder cone on the slopes of Mauna Kea and is fed primarily by winter storms (Ehlmann et al., 2005), though there is concern over recent declining lake levels (Patrick and Kauahikaua, 2015). Pu'upōhaku pond (4000 m) is a nearby sporadic pond that was only recently recognized (Leopold et al., 2016). Given the porous nature of basaltic lava (which cannot hold water to form lakes), the causes of these permanent water bodies on Mauna Kea remain unknown.

Cultural Significance and Human Impacts

Globally, alpine environments are associated with cultural identity, spiritual practices and religious ceremonies, and the provision of ecosystem services such as food and water, natural hazards regulation, and tourism and recreation (Palomo, 2017). The mountains of New Zealand are immensely important to the Māori way of life and sense of place, with individual peaks seen as

representations of ancestors (Pawson and Egli, 2001). Human impacts on the vegetation since the arrival of the Māori ~1000 years ago, however, have been pervasive. Fires in the region significantly altered the vegetation composition, allowing high-alpine plants to extend their ranges into low-alpine tussock grasslands (Halloy and Mark, 2003). European discovery and settlement of this region occurred in the 17th century (Pawson and Egli, 2001) and subsequent economic interests in the region included a brief gold rush, logging, coal mining, and agriculture (Balcar and Pearce, 1996), followed by a tourism boom in the late 20th century. Hiking, hunting, fishing, and skiing/snowboarding are permitted in many of the country's high elevation parks, nature reserves, and scenic areas, although special protected areas of high conservation value have been designated within them (Fig. 3B, Fig. 4A,B) (Mark et al., 2013). Today New Zealand's nature tourism industry generates 6% of the country's GDP and attracts upward of 3 million international visitors a year; only the dairy industry contributes more to the national economy (Stats, 2017). "Glacier Country" in the Southern Alps alone receives over 600,000 visitors a year between Franz Josef and Fox Glaciers (Purdie, 2013).

Native Hawaiian tradition states that deities reside in the high mountain summit areas of the archipelago, and Mauna Loa, Mauna Kea, and Haleakalā are therefore regarded as sacred places of great spiritual importance. The summit of Mauna Kea, the tallest point in Hawai'i, is extremely culturally significant as its peak is considered the *piko* (umbilical cord) of the Hawaiian spiritual world, connecting the Earth, heavens, and stars (Ho'akea, 2009). Lake Waiau is culturally significant to Native Hawaiians as a source of healing water used for ceremonies and worship (Ho'akea, 2009). Most of Hawai'i's alpine regions fall into various conservation zones, which have historically shielded them from development and other human impacts. Nevertheless, Haleakalā National Park on Maui is visited by 1–2 million people a year, established roadways and trail networks provide relatively easy access to all alpine sites, and the construction and operation of astronomical observatories—particularly those near the summit of Mauna Kea—have been the subject of debate for decades due to their impacts on native ecosystems and culturally important sites (Fig. 4C,D) (Hilberg et al., 2018).

Current Changes

Changes in Native and Invasive Species

In New Zealand's Southern Alps, extensive radiations of vertebrate and invertebrate alpine communities have been facilitated by the relatively recent tectonic activity and partial glaciation (Wallis and Trewick, 2009), most notably plants and some birds, such as the

kea (*Nestor notabilis*) and rock wren (*Xenicus gilviventris*) (Fig. 5A,C). Like other oceanic islands, New Zealand has very high rates of endemism (around 30% of plants and 82% of animals; Gordon, 2013); many of the endemic birds are partially or completely flightless (e.g., South Island takahē (*Porphyrio hochstetteri*), Fig. 5B). In the alpine region, over 90% of plants are endemic (Halloy and Mark, 2003). O'Donnell et al. (2017) recently identified 24 native alpine bird species that are characteristic of the Southern Alps region, 17 of which are considered to be at risk. Cold-tolerant lizards (including geckos and skinks), invertebrates like the wētā (*Deinacrida* species) (Fig. 5D), cicadas, giant carnivorous land snails, butterflies, moths, giant wingless stoneflies, and freshwater fish are among the other indigenous biota found at these high altitudes (O'Donnell et al., 2017). The kea, the world's only alpine parrot, was the target of an official campaign from the late 1800s until 1971 to reduce their numbers due to attacks on farm animals (Young et al., 2012), and the New Zealand Department of Conservation (2017) estimates that there are fewer than 7000 today. During the growing season, kea feed extensively on fruiting plant species in the alpine region and as the only species that is known to fly long distances between mountains and ranges, they are significant contributors to alpine plant dispersal in New Zealand (Young et al., 2012).

In the alpine and subalpine ecosystems of Hawai'i, 84% of floristic species are endemic, with more species on Maui than Hawai'i Island despite a much smaller land area and elevational range (Price, 2004). One of the most iconic endemic alpine species, the Hawaiian silversword, is extremely vulnerable to warmer and drier conditions that have been experienced in recent decades (Krushelnycky et al., 2013). The Hawaiian alpine Wēkiu bug (*Nysius wekiuicola*), first discovered in 1979, is a rare endemic, flightless insect species found within a narrow elevation range (3415–4205 m) in the alpine stone desert zone of Mauna Kea that survives on wind-borne insect carcasses blown up from lower elevations (Stephenson et al., 2017). Seabirds, such as the 'ua'u (Hawaiian petrel, *Pterodroma sandwichensis*), are also observed throughout Hawai'i's alpine regions (Banko et al., 2001), and alpine grasslands and shrublands also provide habitat for the endangered state bird of Hawai'i, the nēnē (Hawaiian Goose, *Branta sandvicensis*) (Fig. 5E).

The Hawaiian Islands once had abundant endemic avian biota. Mosquito-borne avian pox and avian malaria, however, have resulted in widespread mortality of forest birds and a shift to higher elevations where colder temperatures inhibit mosquito reproduction (Liao et al., 2015). 'Ōma'o (*Myadestes obscurus*), one of only two remaining species of endemic solitary birds, have been

Fig. 5 Endemic alpine and subalpine fauna. New Zealand: (A) Kea; (B) Takahē; (C) Rock Wren; (D) Alpine Scree Wētā (*Deinacrida connectens*). Hawai'i: (E) Nēnē; (F) Palila. observed in the scrub alpine environments of Hawai'i Island where they are vulnerable to predation by cats and rats (Judge et al., 2012). They, like most of Hawai'i's native forest birds, have lost an enormous proportion of their native range (estimated 70%) due to land cover change and nonnative species invasions, impacts that are expected to be exacerbated by projected changes in climate (Fortini et al., 2015). The palila (*Loxioides bailleui*), a species of critically endangered Hawaiian honeycreeper (Fig. 5F), is almost entirely dependent on the endemic subalpine māmane tree for its food, and has experienced drastic range reductions due to browsing pressure from introduced ungulates that have degraded its habitat. This species is at high risk for extinction with the simultaneous threats of drought, wildfire, and invasive ungulates (Banko et al., 2014).

The alpine regions of the world are often viewed as being relatively resistant to biological invasions, due to their extreme climate and inaccessibility to humans (Pauchard et al., 2016). However, climate change, human-driven environmental degradation, and land use change facilitate species invasions, to which the isolated alpine ecosystems in the Pacific Islands are particularly vulnerable.

The first known mammalian predator to arrive to New Zealand was the Polynesian rat around 800 years ago, but the vast majority of pests were introduced after European settlement in the 1800s (Wallis and Trewick, 2009). Feral populations of red deer (*Cervus elaphus scoticus*) and rabbits (*Oryctolagus cuniculus*) exert significant pressure on New Zealand's alpine grasslands above the treeline, while grazing livestock (primarily sheep, *Ovis aries*) also influence the vegetation cover and species makeup. In particular, native tussocks have declined in favor of invasive herbs in areas with a long history of summer livestock grazing (Norton and Young, 2016). Significant reductions in red deer populations in the Southern Alps have led to the recovery of native shrublands and grasslands in both number and size, however, suggesting that long-term management practices and exclusion of ungulates from sensitive areas can lead to successful restoration (Tanentzap et al., 2009). Himalayan tahr (*Hemitragus jemlahicus*) (Fig. 6A) was introduced to New Zealand's Southern Alps in 1904 as a hunting resource, which reproduced rapidly and reduced native tussock plant species to bare ground. While some efforts to reduce their numbers have been made, the population has continued to increase with long-term impacts on native alpine grassland communities (Cruz et al., 2017). New Zealand's ground-dwelling native alpine birds are particularly susceptible to predation by invasive mammals, including feral cats, stoats, and mice, which have been primarily responsible for their decline (Weston et al., 2018). Alpine populations of endangered takahē and rock wren have been extensively reduced by stoats (*Mustela erminea*) (Fig. 6B) (O'Donnell et al., 2017). Almost half of the country's endemic birds have gone extinct, while limited remaining populations are more vulnerable to changes in climate, extreme events, and disease (Innes et al., 2010).

Invasive ungulates, including pigs, cattle, and goats, have also severely impacted Hawaiian alpine ecosystems at various times over the last 200 years, particularly above the TWI in grassland-dominated areas (Daehler, 2005). This has coincided with soil erosion and nonnative plant invasions that have further reduced alpine plant community regeneration (Daehler, 2005). While goat and cattle populations have been greatly reduced on Hawai'i Island, feral sheep and mouflon have not yet been eradicated. Goats were eradicated from Maui in 1989 but axis deer are increasing in number (Hess, 2016). Removal of ungulates from a subalpine region of East Maui resulted in significant increases in relative cover of native shrubs and ferns, and a decrease in alien grass cover (Hughes et al., 2014). Other invasive mammals, such as cats and mongooses, are rarely observed in Hawai'i's alpine locations, but are still a concern (Fig. 6D). Mice and rats, however, persist at all elevations and are especially abundant near food sources and visitor sites (Vanderwoude et al., 2015). Invasive social insects, such as the Argentine ant (*Linepithema humile*) that has been documented at Haleakalā National Park for the past 25 years (Hartley et al., 2010), have the potential to alter alpine native invertebrate communities and may enter new habitat ranges as the climate continues to warm, disturbing native ecosystems as well as visitor sites (Vanderwoude et al., 2015).

Transportation networks are a main driver species introductions to mountain systems (Alexander et al., 2016), and recreational tourist visitation to Haleakalā National Park, Mauna Kea, and Mauna Loa has facilitated the introduction of invasive plant seeds, pathogens, and insects into higher elevations in Hawai'i (Daehler, 2005). Backcountry huts in New Zealand have also been identified as important sites for invasion by nonnative plant species into remote alpine areas (Lloyd et al., 2006). The area around Lake Waiau on Mauna Kea experiences high levels of visitation via trail and has been invaded by common dandelion (*Taraxicum officinale*) and two species of beetle (*Agonum c.f. muelleri* and *Trechus obtusus*; Vanderwoude et al., 2015). Vegetation surveys along roadsides at Mauna Loa's upper elevations conducted 50 years apart (1958–2008) revealed a significant increase in the number of both native and invasive plant species. The reasons for the establishment of new species remain unclear, but are more likely due to increased human impacts and access than climate warming in this arid and sparsely vegetated environment (Juvik et al., 2011). On Mauna Kea, invasive grasses pose a serious threat to the ecosystems, both in terms of composition and fire risk (Banko et al., 2014), and introduced weeds are abundant in the alpine zone in New Zealand, including hawkweed (*Hieracium* species) (Steer and Norton, 2013). Conifers introduced to the windward slopes of Haleakalā as part of an early 20th century forestry initiative are moving into higher elevations and outcompeting native shrub species (Fig. 6C) (Pauchard et al., 2009). Introduced *Pinus contorta* (lodgepole pine) in New Zealand has also increased at high elevations by 180% over the past 20 years and is now found up to 270 m higher than previously established (Tomioolo et al., 2016). Planted *Pinus radiata* (Monterey pine) was found to reduce water yield by 43% compared to native snow tussock (Mark and Dickinson, 2008).

Observed Climate Changes and Impacts

Since 1900, New Zealand's mean annual temperatures have risen at a rate similar to the global mean, with most of the warming occurring after 1946 ($0.12\text{--}0.14^\circ\text{C decade}^{-1}$, 50-year trend ending in 2006, Dean and Stott, 2009). However, irregularities in observations and poor station coverage in alpine areas result in uncertainties in warming rates for high elevation areas (de Freitas et al., 2014). What is known, however, is that warming has reduced New Zealand's glacier volume since 1850 (Mark et al., 2006). In a recent glacier inventory, Chinn et al. (2012) found that the melting of the region's 12 largest glaciers accounts for 71% of total glacial volume loss in the last 30 years, while the melting of thousands of small- and medium-sized glaciers accounts for the remaining 29%. In total, ice volume in the Southern Alps has been reduced by 18.4 km^3 , or 34%, since 1977 (Chinn et al., 2012), and glacier retreat and reductions in snowfall have impacted tourism operations, with a shift to helicopter-oriented glacier tours (Purdie, 2013) and increased artificial snow-making for skiing and snowboarding (Hopkins, 2014). Despite the expectation that climate-induced warming will cause an upward shift in treeline in alpine locations worldwide, study of treeline areas dominated by *Nothofagus* (beech) in the Southern Alps has shown little response to recent temperature increases (Harsch et al., 2012). Precipitation over the past three decades has trended toward drier conditions on the west coast of the South Island, while wetter trends are found for the west coast (Salinger and Mullan, 1999).

Hawai'i's highest elevations have experienced rapid warming in the last four decades (Giambelluca et al., 2008). The Mauna Loa Slope Observatory (MLO) station, located at 3341 m elevation, has experienced a mean warming trend of $0.19^\circ\text{C decade}^{-1}$ between 1955 and 2016 (McKenzie et al., 2019). This strong warming trend has been linked to degradation of the permafrost on Mauna Kea, which has shrunk by an order of magnitude between 1973 and 2015 (Schorghofer et al., 2017). Based on historical accounts, snowfall used to be much more common on Mauna Kea, but in the modern climate snow occurs only a few times in winter and rarely in summer (Schorghofer et al., 2014). High elevation areas have experienced significant drying since 1920, particularly in the dry season (May to October; Frazier and Giambelluca, 2017). This is consistent with the observed increases in high elevation solar radiation and decreasing cloud cover since 1988, driven by changes in the TWI (Longman et al., 2015a). An abrupt shift in TWI in 1990 resulted in a 20% increase in mean TWI frequency, likely driven by increased intensity of Hadley Cell subsidence near the Hawaiian Islands (Longman et al., 2015a). This shift in TWI has been linked to ecological responses, such as the decline in the Haleakalā silversword population (Krushelnysky et al., 2016).

Future Projected Climate Changes

Alpine ecosystems may be the most affected by global climate change. Alpine climates are extremely complex due to the interactions between mountains and atmospheric circulation. A lack of high spatial and temporal resolution observations, coupled with the limitations of general circulation models (GCMs) in representing the complex terrain, restricts our understanding of these climates (Beniston et al., 1997). Representing complex topography on small islands in climate models is even more challenging, as the differences between land and ocean climates are stark. In Hawai'i, the entire state may fit into only a few grid cells in a GCM, and these coarse-resolution products are not able to simulate the complex processes that operate on relatively small scales (Elison Timm et al., 2015). To overcome these limitations in Hawai'i and New Zealand, various downscaling methods are employed to generate local- and regional-scale projections from the global models.

According to mid-range scenario projections for New Zealand's climate, by 2040, temperatures are expected to increase by 0.8°C , doubling again to 1.6°C by 2110, with the strongest warming over higher elevations. Rainfall will likely increase in the west and decrease in the east and north due to an increase in westerly winds; extreme daily wind speeds will be stronger, especially in the Southern Alps (Ministry for the Environment, 2018). Model projections for snowfall in popular ski destinations suggest dramatic cuts in the number of snow days averaged across all sites by 2040 (up to 24%, depending on the climate scenario) and catastrophic reductions (up to 68%) by 2100 (Hendrikx and Hreinsson, 2012). As in other glaciated areas of the world, New Zealand may lose

88% of ice volume by the end of the century, driven largely by reductions in snowfall (Shannon et al., 2019); by 2100 Franz Josef Glacier could lose 38% of its volume (Anderson et al., 2008). In addition to the gradual loss of alpine glaciers and permafrost as indicators of climate change, there may be a greater risk of landslides and rockfalls associated with short-term temperature extremes, although this has not been confirmed in New Zealand's Southern Alps (Allen and Huggel, 2013). Species-area modeling results show that a 3°C rise in temperatures could lead to a loss of 33%–50% of native alpine plant species, and > 100 new exotic species (Halloy and Mark, 2003). The loss of snow cover due to a warming climate may impact the frost-resistance of alpine plant species (Bannister et al., 2005). Reduced snow cover will likely result in more thermal stress for alpine cockroaches (*Celatoblatta quinque-maculata*) (Sinclair, 2001), while warmer temperatures are expected to reduce and displace populations of alpine grasshoppers (*Paprides nitidus*) (White and Sedcole, 1991). A recent transplant experiment found that some alpine plant communities had inherent resilience to altered snow cover, while novel biotic interactions such as herbivory and competition affected survival (Lord et al., 2018). In addition to warming, patterns of rainfall, wind, and snow cover as well as human disturbances and invasive species behavior will also change in complex ways, and there is still much that is unknown about the response of native species to these changes (Halloy and Mark, 2003).

For Hawai'i, future projections of temperature indicate robust warming statewide, with the greatest warming also at the highest elevations (projections range from 3.5°C to 5°C warmer temperatures by 2100; Elison Timm, 2017; Zhang et al., 2016). Future projections of rainfall are less certain. General patterns indicate that windward areas will become wetter or stay the same, while leeward areas will become drier by the late 21st century (Elison Timm et al., 2015; Zhang et al., 2016). TWI projections indicate a robust increase in the frequency of TWI days, from 82% to 91% on Hawai'i Island, and a decrease in mean base height (Zhang et al., 2016). End-of-century snowfall simulations indicate that snow will nearly disappear on the summits of Mauna Kea and Mauna Loa, with implications for the Hawaiian language name "Mauna Kea," which means "white mountain" (Zhang et al., 2017). As for the ecological impacts of these changes, very little is known about species- or community-level impacts of climate change on alpine ecosystems in Hawai'i. However, given the evidence for a moisture-driven treeline (e.g., Crausbay et al., 2014), a lower and more frequent TWI combined with an increase in El Niño event frequency could depress any upward movement, possibly resulting in downslope migration of the treeline.

Concluding Remarks

Climate change, introduced species, and human impacts have independent and interacting effects on alpine ecosystems globally. On the one hand, the harsher climate of alpine environments and reduced anthropogenic disturbance have historically prevented the establishment of nonnative biota (Alexander et al., 2016), but warming temperatures are alleviating those unfavorable conditions (Pauchard et al., 2016). Similarly, human influence can exacerbate the impacts of climate change while facilitating further introduction and establishment of introduced organisms into new ranges. Native species in these regions—especially those in low densities—may also lack adequate baseline information and are uniquely vulnerable to major threats such as global climate change and human impacts. Resource managers are therefore challenged with accommodating multiple-use natural areas (conservation, public hunting, tourism, cultural use, etc.) while monitoring and managing for ecosystem change with limited information.

The need to track changes in Pacific Island alpine environments is clear: they are rare, isolated (geographically and by elevation), and are uniquely sensitive to the threats posed by climate change, introduced species, and human impacts. Two field sites in the Southern Alps were recently incorporated into the Global Observation Research Initiative in Alpine Environments (GLORIA) project, which was founded in 2001 to monitor vegetation and climate in target high elevation regions worldwide (Mark et al., 2006). The Haleakalā Climate Network (HaleNet), established in 1988, monitors 13 climate variables at eight stations along two transects (windward and leeward) in Haleakalā National Park from 960 to 2990 m elevation (Longman et al., 2015b). The 30-plus years of data gathered here provide an invaluable monitoring dataset for the State of Hawai'i. Other alpine areas, however, are severely lacking climate information. Additional monitoring and research are needed to better understand the sensitivity of these diverse ecosystems to the simultaneous threats of climate change, invasion, and human-driven degradation.

Abstract

Deserts are biodiverse places where life thrives in the extremes. Deserts cover roughly one-third of the Earth's surface, exist on every continent and in hot (subtropical), cool coastal, and polar climates (the Arctic and Antarctica deserts are covered in the Polar Biome section). Eleven of the world's largest (> 50,000 km²) deserts are in Asia, 7 in Australia, 5 in North America, and 2 each in Africa and South America. Deserts are biodiverse places with many endemic life forms uniquely adapted to some of the most extreme terrestrial environments on Earth. Many species are threatened by agriculture and aquaculture, energy development, desertification, unabated collection of plants and seeds for horticulture and private ornamental collectors, livestock overgrazing, invasive plants, off highway vehicles, and climate change.

What Are Deserts and Where Are They Found?

With annual rainfall < 25 cm, deserts are dry for most of the year. Deserts cover roughly one-third of the Earth's surface, spanning polar, subtropical, temperate, and cold climates. Most of the world's subtropical-hot deserts occur from 20 to 35 degrees north and south of the equator with temperate deserts at mid latitudes. While there are different climatic classification schemes for grouping deserts (e.g., Köppen climate classification BWh, BWk, BWn; <https://www.britannica.com/science/Koppen-climate-classification>), in this section, we cover hot (subtropical), cool coastal, and cold winter deserts (Table 1, Fig. 1). Polar deserts (Arctic, Antarctica) are in the Polar Biome section. We focused on a reasonable representation of the Desert Biome globally with all articles following broad topical themes such as biodiversity, conservation importance, status, and management needs.

In general, the movement of air masses that rise and compress moisture over vast areas create dry conditions for deserts to persist. But not all deserts are in the dry interior of continents. Some like the Namib in Africa and Atacama in Chile are coastal; this generally is due to air masses lacking moisture associated with cold oceanic currents. In sum, 11 of the world's largest (> 50,000 km²) deserts occur in Asia, 7 in Australia, 5 in North America, and 2 each in Africa and South America (Table 1, Fig. 1). Smaller deserts, while important ecologically, are also covered in this section. For example, the Baja is addressed here, but could also have been placed in the larger Sonoran region. However, we kept the Sonora as a separate region because of the restricted distribution of Saguaro cactus (*Carnegiea gigantea*), the main indicator species found only in the United States.

Deserts Are Biodiverse Places

If you know where and when to look, deserts are teeming with life (<https://www.conservationmagazine.org/2015/03/deserts-teem-with-biodiversity-if-you-know-where-to-look>). While they are places often with very sparse vegetation, desert occupants are uniquely adapted to low moisture, extreme temperatures (e.g., hot in the day, cold at night; winter in places), and scarcity of resources (mainly water). There are numerous endemic plants (e.g., cacti of the Chihuahua, Sonoran, and Baja deserts) and many specialized animals (especially reptiles and invertebrates) that thrive under these conditions.

Witness the largest cactus in the United States, the Saguaro (Fig. 2). Its ridge-like "skin" (outer surface) is covered with a thick waxy layer that serves to reduce water loss from evapotranspiration. Remarkably, the surface contracts and expands with the availability of water. Thorny hard spines ("leaves") with reduced surface area prevent evaporative loss. To get at subsurface water, the Saguaro sends out a single tap root that descends like a giant straw to nearly 2 m. Additional root masses nearer the surface soak up rainfall during periodic monsoons.

Many desert animals are nocturnal, escaping extreme diurnal heat by burrowing into the soil or sand (e.g., numerous reptiles, rodents, and arthropods). Some take advantage of brief periods when water is available (e.g., monsoon and flash floods). Sonora desert toads (*Bufo alvarius*), for example, emerge from their summer burrows (or rodent holes) during wet periods to reproduce.

Table 1 World's largest deserts (>50,000 km²) grouped by regions.

Name	Type	Area (km ²)	Region
Saharan	Subtropical	> 9 million	North Africa
Kalahari	Subtropical	900,000	South Africa
Arabian	Subtropical	2.3 million	Western Asia
Gobi	Subtropical	1.3 million	Eastern Asia
Syrian	Subtropical	520,000	Western Asia
Karakum	Cold winter	350,000	Central Asia
Kyzylkun	Cold winter	300,000	Central Asia
Taklamakan	Cold winter	270,000	Central Asia
Thar	Subtropical	200,000	South Asia
Daht-e Margo	Subtropical	150,000	South Asia
Registan	Subtropical	146,000	South Asia
Dasht-e Kavir	Subtropical	77,000	South Asia
Dasht-e Kavir	Subtropical	52,000	Central Asia
Patagonian	Cold winter	620,000	South America
Atacama	Cool coastal	140,000	South America
Great Basin	Cold winter	492,000	Western North America
Chihuahuan	Subtropical	450,000	Western North America
Colorado Plateau	Cold winter	337,000	Western North America
Mojave	Subtropical	310,000	Western North America
Sonoran	Subtropical	124,000	Western North America
Great Victoria	Subtropical	348,750	Southwestern-Central Australia
Great Sandy	Subtropical	267,250	Northwestern Australia
Tanami	Subtropical	184,500	Northcentral Australia
Simpson	Subtropical	176,500	Northeastern-Central Australia
Gibson	Subtropical	156,000	Westcentral Australia
Little Sandy	Subtropical	111,500	Westcentral Australia
Strzelecki	Subtropical	80,250	Southcentral Australia

Fig. 1 Continental distribution of world's largest deserts (www.mapsofworld.com). Note: different datasources were used for **Table 1** and **Fig. 1** and thus there are differences in the table compared with the figure.

Fig. 2 Saguaro of the Sonora desert. Note the surface ridges on the Saguaro cactus (left of center) (photo: Julia Sittig with permission).

Fig. 3 The highly adaptable desert camel, Mauritania region (photo: with permission, JC Brito, this section).

Contrary to popular belief, the “hump” of the camel (e.g., *Camelus dromedaries*, **Fig. 3**) does not store water but rather is a reservoir for energy-rich fat important when food is scarce.

When and where water appears, the desert comes to life with a kaleidoscope of flowering plants (e.g., see great Atacama bloom of > 200 flowering plants—<https://www.nationalgeographic.com/news/2017/08/chile-atacama-desert-wildflower-super-bloom-video-spd/>; <https://www.thisischile.cl/the-desert-in-bloom-a-natural-wonder/?lang=en>) producing abundant nectar for a profusion of pollinators. Endemic species like the desert pupfish (*Cyprinodon* spp.) are restricted to rare desert oases (Quitobaquito springs). In other places, tiny rock ponds, called *gueltas* in Mauritania (Sahara-Sahel; northwest Africa), can be as small as 100 m² but function as localized biodiversity “hotspots” (Vale et al. 2015). Ephemeral ponds (**Fig. 4**) provide watering holes for thirsty animals and reproduction sites for insects and amphibians on a short-life cycle clock before the holes dry out.

Some deserts are also noted for their distinguishable sand dunes (**Fig. 5**). Carnivores such as the brown hyaena (*Hyaena brunnea*), also known as the strandwolf, are the rarest of hyaena species (listed as nearly threatened by IUCN red list citation) in African deserts (**Fig. 6**). The largest remaining population is in the southern Kalahari and coastal southwest Africa.

Benefits and Uses of Deserts

Deserts have historically provided homes for human settlements as they do today with >1 billion people that call deserts their homeland (<https://www.nationalgeographic.com/environment/habitats/deserts/>). According to the UN, nearly half of the world’s population in 2030 will be living in areas of high water stress under threat of climate change (https://www.un.org/en/events/desertification_decade/whynow.shtml).

This is critically important as most desert inhabitants live in developing countries in poor economic and social conditions exacerbated by land degradation and difficult access to water and food (<https://en.wikipedia.org/wiki/Desertification>) that will only intensify in a changing climate.

Notably, German particle physicist Gerhard Knies calculated that in 6 h, the world’s deserts receive more energy from the sun than humans consume in a year. An $\sim 21,000 \text{ km}^2$ stretch of Saharan desert—an area the size of Wales—could power all of Europe. With water present, deserts provide countless agricultural products. Some examples of crops grown include melons, apples, green onions, cucumbers, corn, peppers, radishes, carrots, cabbage, soybeans, pears, tomatoes, squash, spinach, date palms, and alfalfa (for livestock). Desert salts also contain important minerals such as gypsum, borates, nitrates, potassium and other salts exposed when water dries up. From a recreation standpoint, many desert canyons are known worldwide for their exceptional white-water rafting and hiking opportunities and for visiting archeology sites to learn about civilizations (Fig. 7A and B).

Goldstein).

Conservation Status

Globally, deserts are under enormous pressures (Figs. 8, 9) from land conversion (agriculture and aquaculture, and more recently energy development), unabated collection of plants and seeds for horticulture and private ornamental collectors (e.g., cacti in the Americas), livestock overgrazing (Wuerthner this section), invasive plants (Rogers this section), and climate change (Goettsch et al. 2015). Alarming, 31% of the 1478 cacti evaluated by researchers are threatened with extinction (Goettsch et al. 2015). The entire Cactus family (endemic to the Americas) is on CITES Appendix II, with the most endangered species on Appendix I (<https://www.iucn.org/ssc-groups/plants-fungi/cactus-and-succulent-plants-specialist-group/cites-species>). As reported by IUCN, TRAFFIC North America estimates that between 1998 and June 2001 nearly 100,000 succulents, with an estimated value of \$3 million were taken from Texas and Mexico for the garden market in Arizona.

Many succulents are of interest to the horticulture industry (which artificially propagates them) because of their unusual growth forms and characteristics. They are used for food, fodder, fiber, shelter, medicines (e.g., *Aloe vera*, *Agave*, *Euphorbia* spp., *Dioscorea deltoidea*), oils and cosmetics (e.g., *Aloe*).

As far as grazing pressure in the high-altitude deserts like the Great Basin in North America (Fig. 8), the combination of alien species and more frequent novel fires have transformed much of the native vegetation resulting in extensive biodiversity losses

Fig. 8 Matched photographs (A and B) illustrate the loss of native vegetation common in deserts around the world. The first photo (A), taken in 1901 by geologist G. K. Gilbert shows Gilbert's horse Sally (public domain photo) beside a boulder in a salt desert shrubland typical of lower valleys across the Great Basin Desert of North America. The second photo (B), taken in 2008 (photo: with permission, G. Rogers, this section), shows the same location but with few remaining shrubs and only a thin thatch of summer-dried remains of invasive *Bromus tectorum* and other alien annual weeds.

(see Wuerthner this section). Notably, unusually severe fires in Sonora have been devastating to ancient Saguaro cactus that did not evolve with “crown” fires now more prevalent in the system due to the spread of exotic cheatgrass from livestock grazing.

The articles in this section provide a synopsis of the multitude of uses and threats (most are increasing) as summarized in Fig. 9.

Finally, desertification is an expanding threat to many desert systems world-wide that are being impacted by the loss of native plants and increased sandstorms from overgrazing, over farming, and climate change. Efforts are underway in the Gobi desert, for instance, to plant over a billion trees (China's “green wall”) to combat desertification (which is associated with rural poverty); however, this has had questionable results (see <https://www.motherjones.com/environment/2017/08/china-plants-billions-of-trees-in-the-desert/>). Some 119,139 km² of arable land turn to desert every year due to climate change and practices such as forest clear-cutting (<https://worldpreservationfoundation.org/environment/desertification/>, accessed September 6, 2019). Desertification threatens the livelihoods of > 1 billion people in 110 countries (https://www.un.org/en/events/desertification_decade/value.shtml, accessed September 4, 2019), representing an economic loss of US\$42 billion per year.

Conservation Needs

Popular perceptions of deserts are vast wastelands in post-apocalyptic scenarios that you just do not want to be stuck in. But the Desert Biome overall is highly complex; rich in species, rarity, and endemism; and is one of the most misunderstood biomes on the planet.

Deserts in fact are places where nature not only persists but thrives in temporal and spatial hot spots of biological activity. Much of the biodiversity is concentrated in vernal pools and is present during seasonal monsoons that trigger a kaleidoscope of flowering plants, pollinators, and many other species. Deserts are also highly threatened by a host of human activities conspiring with

Fig. 9 Threats facing desert systems: (A) oil exploration in Niger; (B) eutrophication from livestock grazing in Mauritania; (C) garbage from excessive tourism in Algeria; (D) road impacts in Algeria; (E) large settlement in Niger; (F) poaching of white antelope *Addax nasomaculatus* and Barbary sheep *Ammotragus lervia* in Mauritania (photos: with permission, JC Brito, this section); and (G) livestock damage (changes in channel morphology, cut bank erosion, loss of native plants) in the Tonto National Forest, Arizona (photo: with permission, G. Wuerthner, this section).

unprecedented climate change that will push much of the biota past a threshold of where not even their unique adaptations will allow them to persist in the more extreme conditions (e.g., temperature/precipitation changes outside climate envelopes). The authors of this volume summarize the unique biodiversity values of their region, threats to persistence of desert features, and conservation needs. For example,

- Smith and Pettorelli (this section) provide a comprehensive introduction to desert ecosystems and conservation challenges.
- Rogers (this section) states that advanced planning and public support are essential for prevention and control of invasive weeds that are altering desert systems globally, creating vast weedy wastelands.
- Mills (this section) describes the arid Kalahari, containing the Kgalagadi Transfrontier Park, as the only functional large carnivore community in an African desert, and possibly anywhere else on earth.
- Santarém (this volume) outline the potential for and limitation of ecotourism in preserving the desert biome while supporting local cultures, traditional livelihoods and sustainable development goals.
- Brito and Pleguezuelos (this volume) discuss how the desert biome comprises highly adapted species, harboring about 25% of continental vertebrate species in places, and how increasing exploitation activities and climate change threaten biodiversity.
- Austin et al. (this volume) provide an overview of one of the most relatively intact high desert ecosystems on Earth, the Northern Great Basin United States, that is under threat from agriculture, livestock grazing, housing and energy development, altered fire regimes, invasives, and loss of riparian systems.
- Malakoutikhah and Hemami (this volume) discuss that despite the extraordinary biological diversity levels in deserts world-wide, only 9–11% of the biome is in protection status with ~7% in protected connected habitat status.
- Wuerthner (this volume) demonstrates how desert regions due to natural aridity, climate extremes, and limited vegetative production are especially vulnerable to impacts from domestic livestock production.
- Laverty (this volume) describes the unique biodiversity found in one of the world's oldest deserts, the Namib Desert, with a focus on the often-overlooked bat community that lives among desert-dwelling megafauna in the Namib's northern reaches.
- Briggs et al. (this volume) describe one of the most biologically diverse and endemic rich deserts, the Chihuahuan, that faces numerous threats requiring a coordinated binational response.
- Vale et al. (this volume) describe species distribution patterns in the Sahara-Sahel where α -diversity (local species number) follows general latitudinal gradients in species richness with high richness also along corridors and refugia while hotspots define β -diversity gradients. Isolated and residual wetlands constitute hotspots in need of conservation.
- Bradley and Colodner (this volume) provide an overview of the Sonoran Desert, one of the most distinctive ecoregions in the world, and its unique biota that are under threat from climate change, invasive species, livestock grazing, land conversion, and the US/Mexico border-wall.
- Nussear and Esque (this volume) discuss the biogeography of hottest and driest of the four North American deserts, the Mojave, its unique species, and conservation challenges in a changing climate with increasing land-use pressures.
- Vanderplank and Ezcurra (this volume) describe the biogeographical patterns and ecological processes that have resulted in high levels of endemism and rarity throughout the deserts of the world.
- Anderson (this volume) describes the potential conflicts and solutions between energy and arid ecosystems as the global quest to transition to renewable energy proceeds.

Abstract

The desert biome is usually perceived as bare and rather homogeneous area that exhibit relatively low diversity in comparison to other biomes. However, deserts are surprisingly rich, harboring about 25% of continental vertebrate species and comprising highly adapted and specialized species that are found nowhere else. They display high rates of endemism due to the adaptive processes of organisms to the extreme environmental conditions, as well as locally endangered hotspots of biodiversity. Biodiversity is distributed according to the extreme climatic conditions of deserts, and concentrates in mountains, suitable climatic corridors, and in the rare, generally small, and fragile wetlands. Geological events and palaeoclimatic oscillations largely drove the main evolutionary processes, acting over diversification and speciation events mainly through vicariance. Remarkable and unique adaptations for survival in the aridity, heat, and salinity conditions of deserts are found in species inhabiting these environments. Desert biodiversity is currently threatened by increasing human exploitation activities and climate change. Still, deserts classify as one of the last wild biomes on Earth, where implementing conservation actions would be most cost-effective. Long-term conservation of desert biodiversity requires appropriate policy instruments that promote conservation and sustainable use of natural resources. Raising environmental alertness and pride within local communities of the value and uniqueness of the desert wildlife is needed to pressure strong policy change.

Introduction

Deserts, defined by aridity index (average annual precipitation/potential evapo-transpiration) below 0.05, and arid regions, defined by aridity index between 0.05 and 0.20 (Ward, 2016), represent about 41% of the Earth's land surface and are inhabited by 2 billion people. They are distributed at 25–35 degrees latitude in both the northern and southern hemispheres, and cover six biogeographical realms, Afrotropics, Australasian, Indo-Malay, Nearctic, Neotropical, and Palearctic (UNEP, 2006). They are usually perceived by the general public as bare and rather homogeneous areas that exhibit relatively low diversity in comparison to other regions, which results in attracting less global research funding and scientific attention. However, deserts landscapes are rather diverse (Fig. 1): from flat deserts of rock and sand, such as the Sahara, to rocky mountains emerging from lowland sedimentary plains, as in Central Asia or North America (UNEP, 2006). The climatic variations during the Plio-Pleistocene period, with feedback mechanisms between rainfall reduction and vegetation cover, forced world's deserts to contract during cold glacial periods and to expand during the hot interglacial. The last humid period ended between 6 and 5000 years ago, leading to the current warming and aridity trend. These climate and land-cover oscillations have greatly shifted the extent and limits of world's deserts, and regulated biodiversity patterns and evolutionary processes (Brito et al., 2014). Deserts and arid regions are surprisingly rich, harboring about 25% of continental vertebrate species and comprising highly adapted and specialized species that are found nowhere else (Mace et al., 2005). Furthermore, they display high rates of endemism due to the adaptive processes of organisms to the extreme environmental conditions, as well as locally endangered hotspots of biodiversity (Davies et al., 2012; Murphy et al., 2012; Brito et al., 2014; Vale et al., 2015; Rossini et al., 2018). The extreme climatic conditions of these regions generate sharp landscape and ecological gradients that may be associated with the range limits of many species (Brito et al., 2014). These traits make deserts and arid regions excellent natural laboratories to examine the effects of extreme environments on the distribution of biodiversity patterns (Ward, 2016).

Although most deserts and arid regions still classify as one of the last wild biomes on Earth, they are increasingly threatened (UNEP, 2006; Davies et al., 2012), with negative consequences in the ecosystem services provided by these biomes, such as food, energy, water and livelihood security, as well as, the good physical and mental health of individuals and societies living there. Biodiversity is locally threatened by increasing human exploitation activities and progressive aridity conditions (UNEP, 2006; Brito et al., 2016, 2018). Presently, deserts contain some of the most endangered species in the world (Mace et al., 2005; Durant et al., 2014; Khalatbari et al., 2017), while together with arid lands supporting at the same time nearly a quarter of the world's population

Fig. 1 Landscape diversity across the Sahara-Sahel, the largest warm desert of the world. (A) Sand dunes (Nouakchott, Mauritania); (B) Mountains (Elmeki, Niger); (C) rock-pools (Touia, Algeria); (D) Coastal (Boujdour, Morocco). Photograph credits: José C. Brito.

and some of the most poor and vulnerable people (UNEP, 2006). Increasing poverty and frequency of conflicts have been associated with decline of local wildlife in desert biome (Brito et al., 2018). Furthermore, the magnitude and velocity of climate change in deserts and arid regions are predicted to be strong and fast (UNEP, 2006), which will likely cause biodiversity declines and the desert-adapted species may even be the most vulnerable ones with respect to other terrestrial biomes (Vale and Brito, 2015). Climate-related adversities are also likely to spark regional conflict and further biodiversity loss (Brito et al., 2018) associated to fast-growing human population rates and the ethnical fractioned societies that characterize many countries where deserts are found. These threats are causing growing international awareness for desert biodiversity (UNEP, 2006; Davies et al., 2012; Ward, 2016; Brito et al., 2018).

Biodiversity Research in Desert Biomes

Although deserts and arid regions are highly appealing for biodiversity and evolutionary research, their usual large size and remoteness, and in some cases long-term political instability, contribute substantially to a generalized lack of knowledge (Brito et al., 2014). The African Sahara and the deserts of Central Asia are particularly poorly studied. On the contrary, there are multiple institutions dedicated to desert research and/or research facilities implemented to welcome visitors and researchers in the deserts of North America, Australia, and Namibia. These include in North America the Desert Studies Center (California; <http://nsm.fullerton.edu/dsc/>), Desert Research Learning Center (Sonora; <https://www.nps.gov/im/sodn/drlc.htm>), Desert Research Unit (Arizona; <https://snre.arizona.edu/facilities/dru>) and the Desert Research Institute (Nevada; <http://www.dri.edu/>); in Australia the Desert Ecology Research Group (Sydney; <http://www.desertecology.edu.au/>) and Desert Knowledge Australia (<https://www.dka.com.au/>); and in Namibia the Desert Research Foundation (<http://www.drfn.org.na/>) and the Gobabeb Desert Research and Training Centre (<http://www.gobabebtrc.org/>). The 50 years of work being developed at Gobabeb have allowed gathering a remarkable body of knowledge on multiple subjects, from vegetation ecology to herptile diversity and distribution.

The research efforts in desert environments have increased exponentially over the last decades (Fig. 2). Research is now developed using contemporary tools and analytical processes, including molecular (DNA sequencing and genotyping) and

Fig. 2 Yearly evolution of the number of papers listed in ISI-Web of Science (assessed November 27, 2018) since 1990 with the keywords Desert* and Biodiversit*.

geomatic (Global Navigation Satellite Systems and Geographical Information Systems) tools. Together with broad sampling of taxa, a growing body of studies are starting to reveal and mapping patterns in the distribution of biodiversity, including local hotspots of biodiversity and cryptic diversity, as well as to provide insights on the evolutionary history of multiple taxa, including information on the causes, timing and patterns of radiation and divergence (Brito et al., 2014). Still, these studies are also revealing gaps on these topics and exposing severe threats to biodiversity conservation.

Desert Biodiversity in Numbers

Deserts and arid regions accumulate at least 7000 species of amphibians, reptiles, birds and mammals, of which about 1000 are endemics, distributed in 300 families (Mace et al., 2005). These estimates are remarkably close to the figures displayed by other biomes known to have high levels of species richness, such as tropical grasslands and tropical dry forests. The Sahara-Sahel alone gathers 1147 terrestrial vertebrates, of which 125 are endemics (Brito et al., 2016). Deserts and arid regions are home to 80% of the mammals, birds, and amphibians of North America, around 70% in Europe, Asia and North Africa, and 60% in sub-Saharan Africa and Latin America (Davies et al., 2012). They also support iconic plant groups, such as the cacti and succulents, trees such as Acacia and Baobab, and many of the world's grassland species.

While some deserts display low species richness per unit area, especially the hyper-arid areas of the Sahara, Central Asia or Central Australia, other areas exhibit relatively high levels of species richness, such as the African Sahel, Coastal Arabia or the North American grassland plains, or even exceptionally high number of species per unit area, such as the arid and dry sub-humid areas in the Andes (Davies et al., 2012; Ward, 2016). The African Sahara-Sahel, the Arabian Peninsula and Australian deserts have been shown to display a significant high number of reptiles, especially lizards, in comparison to other tetrapods. Some deserts are particularly rich in endemic phylogenetic lineages, such as the North American deserts for terrestrial mammals, or display high phylogenetic diversity in comparison to the observed species richness, such as the African Sahel for terrestrial birds.

Phylogeographic studies using molecular markers are uncovering additional cryptic diversity in multiple taxonomic groups across world's deserts (Murphy et al., 2012; Brito et al., 2014 and references therein; Silva et al., 2017; Šmíd et al., 2017; Gonçalves et al., 2018a,b; Velo-Antón et al., 2018). In some cases, molecular phylogenies are supporting the splitting of previously considered wide-ranging species (Murphy et al., 2013; Brito et al., 2014 and references therein; Šmíd et al., 2017). Taken together, these studies suggest that the diversity in deserts is still largely underestimated and they are changing completely the perceptions on biodiversity distribution patterns in deserts (Brito et al., 2014, 2016). The predominant idea that deserts accumulate few species with large distributions is being increasingly replaced by evidence showing that larger numbers of species are present and that in some cases they display narrower ranges, often limited to local hotspots of biodiversity (Murphy et al., 2013, 2015a; Vale et al., 2015; Rossini et al., 2018).

Biodiversity Patterns in Desert Biomes

The knowledge of biodiversity distribution in world's deserts is highly biased towards North America and Australia (Fig. 3). The availability of biodiversity distribution data in the Sahara-Sahel, the Horn of Africa, the Arabian Peninsula, and Central Asia is scarce in relation to other global deserts (and biomes). The central portions of these deserts are the most under-sampled areas, which is related to their restricted accessibility and in some cases to the occurrence of armed conflicts (Brito et al., 2014, 2018). For instance, the south of the Arabian Peninsula, the Irano-Anatolian region, and the Central Asian mountains have been shown to potentially display higher reptile richness than currently known and to represent knowledge gaps in the biodiversity distribution. In fact, there

Fig. 3 Distribution of the 1,038,666,838 occurrence records (assessed in 27/11/2018) at the Global Biodiversity Information Facility (GBIF; <https://www.gbif.org/>).

are very few comprehensive and recent distribution atlases available for desert biodiversity, which hampers the identification of regional biodiversity hotspots and optimized conservation planning.

Despite the broad knowledge gaps, multiple patterns emerge in the distribution of biodiversity in deserts and arid regions:

- (1) Biodiversity is not randomly distributed. For instance, the distribution of terrestrial vertebrates in the Sahara-Sahel is spatially structured and apparently it is related to environmental variation: ten biogroups (species assemblages with shared distributions) were identified and wide-range biogroups tend to overlap in specific climate regions (Brito et al., 2016). In Australia, five major *Acacia* biogeographical regions were identified and these match with other bioregionalization exercises. The differences in community composition of aquatic invertebrate communities in Western Australia are associated to the spatial configuration of the dendritic network and to the regional topographic complexity interplaying with local environmental conditions. A global comparison of the distributions of 5000 mammals showed that both high life-history trait diversity and phylogenetic beta diversity are found in deserts and arid regions, and that this diversity is probably related to the environmental heterogeneities of this biome.*****

The increasing use of ecological niche-based models is indicating that biodiversity distribution in deserts can be associated with multiple environmental factors (Brito et al., 2014 and references therein). The distribution of multiple species has been tightly linked to geographical variation in rainfall and temperature (Wilson and Pitts, 2012; Silva et al., 2017; Gonçalves et al., 2018a,b; Rossini et al., 2018; Velo-Antón et al., 2018). In the Australian arid zone, there is asynchronous demographic responses in fecundity, recruitment, and survival of reptiles to rainfall and temporal variability in temperature, during and prior to the breeding season. The geomorphic landform surface composition of the Mojave Desert was shown to be associated with habitat suitability in reptiles. Human activities have also been associated with the distribution, range contraction and population dynamics of large-sized mammals, such as cheetah and gazelles in Southwest Asia (Khalatbary et al., 2017);

- (2) Mountains in deserts constitute refugia for biodiversity particularly for aquatic and mesic species (Brito et al., 2014, 2016 and references therein), and supporting examples are found in multiple taxa (e.g., Šmíd et al., 2017; Gonçalves et al., 2018a). Given the general remote and inaccessible characters of mountains, they also tend to constitute major refugia for threatened large ungulates and carnivores (Brito et al., 2016, 2018). In the Sahara-Sahel, mountains accumulate a significant portion of the regional endemic species and contain many isolated populations of vertebrates of non-Saharan origin (Brito et al., 2016). These populations usually persist in isolated populations restricted to humid habitats and their surroundings and their presence has been associated with temporal distribution shifts linked to Plio-Pleistocene climate fluctuations (Brito et al., 2014 and references therein);
- (3) High biodiversity levels are found along ecological corridors. in deserts and arid regions. In some cases, these corridors are remnants of savannah-like habitats that covered deserts during past humid periods. In the Sahara-Sahel, those corridors have been hypothesized to follow a North-South axis, along the Atlantic and the Red Sea coastal areas, and the Central Sahara mountains (Brito et al., 2014). In the former regions, the mild climate influenced by the proximity of the sea is likely to be related with current high biodiversity levels observed (Gonçalves et al., 2018b; Velo-Antón et al., 2018). Dispersal corridors are linked to the occurrence of secondary contacts during the Pliocene between differentiated lineages of lizards in Australia;
- (4) Given the high aridity levels that characterize deserts high concentrations of species richness are found around the rare wetlands. Oases in sand-seas are crucial for plant, animal, and human subsistence and constitute refugia for multiple aquatic species around the most extreme arid areas (Fig. 4). The spring complexes of the Great Artesian Basin (GAB) in the arid and semiarid regions of eastern Australia constitute exceptional biodiversity hotspot, where 75 of the 326 spring complexes accumulate up to 96 species and subspecies of fishes, mollusks, crustaceans and plants endemic to these springs, and most of the endemics are limited to small and individual spring complexes (Rossini et al., 2018). Molecular studies done with

Fig. 4 Wetlands in deserts constitute local biodiversity hotspots. (A) Hamdoun rock-pool, Mauritania; (B) Umm al Maa lake, Libya; (C) Ounianga Serir lake, Chad; (D) Bilma oasis, Niger. Photograph credits: José C. Brito.

amphipods at the local scale in the Lake Eyre GAB show consistent patterns: pronounced genetic diversity was identified indicating that the levels of endemism in amphipods still need better estimation, many taxa (species and Evolutionarily Significant Units) have highly restricted distributions and are endemic to few springs (Murphy et al., 2013). Mountain rock pools have been identified as local biodiversity hotspots in Sahara-Sahel mountains (Brito et al., 2014 and references therein). Studies in Mauritania have uncovered a system of pools sparsely distributed in temporal riverbeds in mountains that allow the maintenance of rich communities, with many endemic species, and that act as refugia to relict Afro-tropical fauna (Vale et al., 2015). In 69 pools examined, with a mere aggregated extent of 43 ha, they hold about 32% and 78% of the total and endemic fishes, amphibians, reptiles and mammals of Mauritania, respectively. A spectacular example of the biodiversity value of these pools is the presence of crocodiles (*Crocodylus suchus*) in about 100 Mauritanian pools (Fig. 5). Dispersal events between specific pools during the rainy season have been recorded and these are likely related with the distribution of hydrographic basins, water availability patterns, and local human pressures, as well as with the patterns of population structuring found;

- (5) The vast empty-quarters (unpopulated areas) and dune massifs are crucial refugia for threatened species. In the Sahara-Sahel, although these regions exhibit overall low species richness, they accumulate most of the threatened taxa, including birds, large ungulates, and carnivores that suffered extreme declines in other regions because of direct persecution (Brito et al., 2014, 2016, 2018).

Evolutionary Processes in Desert Biomes

Current biodiversity patterns in deserts and arid regions are the result of millions of years of geological events and palaeoclimatic oscillations across Earth. The appearance of the first deserts certainly posed challenges to the survival of species dependent on humid habitats, but also opened up opportunities for diversification in species with tentative adaptations to arid environments. For instance, the increased aridity that followed the onset of the Sahara-Sahel presumably acted mainly as a North-South vicariant feature and it has been linked with diversification processes for several species and to allopatric effects (reviewed in Brito et al., 2014).

The palaeoclimatic oscillations have greatly shifted the climate and land-cover, and in consequence the limits of deserts. For instance, during the Last Glacial Maximum (LGM), the northern limits of world's deserts tended to be colder and more humid in

Fig. 5 West African crocodile (*Crocodylus suchus*) is one of the many Afro-tropical relicts persisting in isolated rock pools of Mauritania (A) adult crocodile basking in Tartêga; (B) habitat in mountain canyon, Garaouel. Photograph credits: (A) Frederico Santarém; (B) José C. Brito.

comparison to the present time, whereas the southern tropical limits were generally drier than in the present time (UNEP, 2006). In response to these climate characteristics of the LGM, the Mediterranean areas of North Africa became wetter and colder, while large dune systems developed along the southern Sahara-Sahel region and in the Thar Desert of India. The magnitude and extent of these range shifts in desert limits, as well as the onset age were distinct across the world's deserts. For instance, in Africa, the Namibe desert is very old (c.55 million year or even older; Ward, 2016) and its range has been rather stable throughout time. On the contrary, the Sahara is more recent (c.7 million year or even younger) and its range has largely shifted in result of rather frequent and intense oscillations between dry/humid periods, following cycles of approximately 100,000–20,000 years during the last million years. These differences in the temporal and spatial variation of desert onset and extent had dramatic consequences over biodiversity distribution patterns (Brito et al., 2014; Ward, 2016). For instance, there was a burst in the development of woodlands of pinyon pines, junipers, and oaks in the Chihuahuan Desert of North America during the late Pleistocene, while the increasing drier conditions in the tropical dry woodlands of central Mexico created the environmental conditions for the evolution of the rich cactus flora that characterizes the region today (UNEP, 2006).

Geological events and palaeoclimatic oscillations largely drive the main evolutionary processes, acting over diversification and speciation events. For instance, molecular dating indicates that the changing climate at the beginning of the Pliocene, from hot and dry to cold and humid, is likely responsible for increased speciation in *Hemidactylus* lizards in the Arabian Peninsula (Šmíd et al., 2017), and the Pleistocene climate oscillations where associated with range expansion and contraction in the velvet ant *Sphaerophthalma difficilis* that led to the formation of genetically distinct populations inhabiting distinct arid regions in the North American deserts (Wilson and Pitts, 2012). The main driver of speciation in the world's deserts is vicariance, when considering a neutral scenario where adaptation processes are discarded. During vicariant events, the geographical separation and isolation of a subpopulation from the original population results in the interruption of gene flow, which ultimately promotes divergence within the original species and differentiation as evolutionarily independent lineages or new species (Fig. 6). In the Sahara-Sahel, it has been shown that ecological traits and habitat requirements play a key role in the timing and nature of the vicariant effects (Brito et al., 2014). In xeric species, adapted to arid environments, the diversification events occurred during the humid periods, followed by range expansions during the dry periods (e.g., Velo-Antón et al., 2018). Conversely, in mesic species, adapted to arid conditions but requiring some level of moisture, the diversification events occurred under hyper-arid conditions when they suffered range contraction into suitable fragmented areas, such as rocky massifs and mountain ranges (e.g., Gonçalves et al., 2018a,b). During humid periods, mesic species may experience population expansions from areas of refugia. The cycles of population expansion during suitable climatic conditions and population contraction during harsh climate conditions have translated into opposing patterns: dispersal along corridors that facilitated gene flow and possibly secondary contact during suitable climatic periods (e.g., Gonçalves et al., 2018a; Velo-Antón et al., 2018), and divergence in the absence of gene flow in refugia and speciation (e.g., Šmíd et al., 2017; Gonçalves et al., 2018b) during unsuitable climatic periods.

Water-dependent species inhabiting deserts are particularly susceptible to climatic oscillations and to water availability. During wet periods, gene flow among populations occurs continuously along permanent or temporary rivers, and during the dry periods these species become extinct or isolated in small wetlands (oases and springs). As expected, divergence events occurred during hyper-arid periods. For instance, the formation of deserts around Lake Eyre in the early Pleistocene led to the hydrological isolation of spring complexes in the GAB and was associated with significant molecular divergence in hydrobiid freshwater snails of genus *Trochidrobina*, supporting the “trapped in desert springs” hypothesis for the diversification of intraspecific lineages in the Australian desert (Murphy et al., 2012). The effects of the dynamics of water availability in promoting diversification events of aquatic species are particular evident in the Lake Eyre, resulting in extraordinary levels of micro-endemism in chiltoniid amphipods: over 13 genetically divergent lineages were recognized as Evolutionarily Significant Units, all of which could be considered as separate

Fig. 6 Schematic representation of hypothetical diversification mechanisms through allopatric processes expected in three types of species: xeric (circles), mesic (squares) and water-dependent species (diamonds). Along the time-series of climatic cycles (from top to bottom), there is expansion of semiarid environments (green) during wet periods, alternated with expansion of arid environments (yellow) during dry periods. The cycles of range expansion-contraction promote the emergence of new lineages (colors) and subsequent contact zones between lineages (black lines). Adapted from Brito, J.C., Godinho, R., Martínez-Freiria, F., Pleguezuelos, J.M., Rebelo, H., Santos, X., Vale, C.G., Velo-Antón, G., Boratyński, Z., Carvalho, S.B., Ferreira, S., Gonçalves, D.V., Silva, T.L., Tarroso, P., Campos, J.C., Leite, J.V., Nogueira, J., Álvares, F., Sillero, N., Sow, A.S., Fahd, S., Crochet, P.-A. and Carranza, S. (2014). Unravelling biodiversity, evolution and threats to conservation in the Sahara-Sahel. *Biological Reviews* **89**, 215–231.

species (Murphy et al., 2013). Climatic oscillations also impacted the hydrological networks and consequently population connectivity, which might prompt vicariant processes, as suggested in Lake Chad and in the Nile River. Landscape connectivity of aquatic fauna in deserts, mostly in fishes and invertebrates in the deserts of Australia and North America, has been shown to decline with increasing geographic scale and to be highly dependent in species dispersal abilities and hydrological connectivity (Murphy et al., 2015b).

Refugia during harsh climatic conditions are pivotal for diversification events in world's deserts. Mountains and wetlands provide persistence areas during periods of unsuitable climatic conditions and then facilitate gene flow during suitable climatic conditions (reviewed in Brito et al., 2014). For instance, the Colorado Plateau and parts of the Great Basin Desert of North America were shown to be refugia during Pleistocene climate conditions for velvet ants, and many other taxa (Wilson and Pitts, 2012). In the case of long-term allopatric isolation in mountains during harsh climatic conditions, divergence and speciation events were observed in *Agama* lizards of the Sahara-Sahel (Gonçalves et al., 2018b) and the topographically complex mountains of southwestern Arabia were associated with a significant radiation in *Hemidactylus* geckos, by allowing multiple allopatric speciation events to occur in relatively small areas (Šmíd et al., 2017). During suitable climatic conditions, mountain populations are at the origin of several episodes of range expansion, promoting the occurrence of gene flow events between previously isolated populations. A spectacular example comes from the desert springs of the Lake Eyre of Australia, which work both as refugia for several endemic faunal groups (isopods, amphipods, ostracods, snails, and beetles) that diverged into multiple lineages before the formation of present-day deserts, and as evolutionary cradles of future biodiversity hotspots by allowing the diversification of novel endemic fauna during isolation periods (Murphy et al., 2015a).

Adaptations to Desert Biomes

Life originally evolved in water and water is the most fundamental element for the survival of almost all living organisms. The imposition of desert conditions forced plants and animals to deal with unpredictable spatial and temporal limitations in water and food resources, and extreme temperatures and solar radiation during the day. As such, organisms inhabiting the world's deserts have either developed unique adaptive features and/or behavioral adaptations to cope with the harsh environmental conditions. For instance, most of the desert-dwelling species tend to avoid exposure or activity during the hottest and driest parts of the day and year. An extreme and most effective way of dealing with harsh desert conditions is the evolution of ephemeral life-cycles, characterized by short-life cycles and resistant propagation forms, found in plants and many invertebrates, such as in the Tadpole shrimps of genus *Triops* (Fig. 7). Many annual plants are able to thrive in deserts by germinating immediately after the rainy season and completing their life-cycles before the onset of the dry season (Ward, 2016).

The most remarkable and unique adaptations for survival in the aridity, heat, and salinity conditions of deserts are found in xeric species, inhabiting the environments where water availability is most scarce (UNEP, 2006). In plants, these include deep root systems in trees and shrubs to exploit deep aquifers, and different gas exchanges levels (with less stomatal control of water loss), leaf shedding periods, and leaf sizes and positions to cope with droughts (Ward, 2016). In animals, these include morphological adaptations related to size and shape that enhance fitness by controlling heat gains or water losses. For instance, larger body size evolved as response to avoid over-heating by increased thermal inertia (when evaporative cooling is not possible) or elongated bodies, wedge-shaped heads and limb reductions evolved multiple times in sand-diving species, such as in the Sandfish of genus *Scincus* (Fig. 7; Brito et al., 2014; Ward, 2016). To minimize body contact with the burning ground surface and to allow to use and to travel fast across open and loose microhabitats, specialized mechanisms of locomotion evolved: the sidewinding locomotion in the case of the Horned vipers of genus *Cerastes* and the bipedalism in the case of small desert mammals, like the Jerboa of genus *Jaculus* (Fig. 7).

Physiological adaptations also evolved, allowing the survival under conditions of low water availability, high heat, or excessive salt. For instance, reduction of resting metabolic rate evolved multiple times allowing more efficient conservation of energy and water, and long retention time of fluid in the gastrointestinal tract has allowed the reduction of overall energy turnover and lowering

the metabolic rate. In some extreme cases, particular adaptations to aridity evolved, allowing even large sized species to persist in environments without water availability, such as the case of the Addax (*Addax nasomaculatus*) inhabiting vast empty quarters of the Sahara desert.

Most of the world's deserts have originated in distinct time periods and have developed in relative isolation from each other (UNEP, 2006). As such, many of the life forms currently inhabiting deserts have evolved from different ancestral forms. The remarkable cases of convergent evolution of desert forms across the globe make desert prime natural laboratories to study and understand the processes behind the development of similar morphological forms and other adaptations derived from different ancestors. Presumably, convergent evolution of desert forms is consequence of the similarities in selection pressures placed on these organisms (Ward, 2016). There are multiple examples of convergent evolution in world deserts, from plants to animals (Table 1). The classic example of convergence is the succulent Cactaceae in the Americas and the Euphorbiaceae in Africa, as is the convergence of stem-succulent tree *Aloe* genus in South Africa and stem-succulent *Yucca* genus in North America (Ward, 2016). Another example is found among the sand-diving skinks, which find representatives across the world's deserts sharing striking morphological and behavioral adaptations.

Threats to Biodiversity in Desert Biomes

World deserts are currently threatened by the synergistic effects of two rather recent processes, the human penetration in this biome with exploitation purposes due to increasing demands and climatic change (UNEP, 2006; Davies et al., 2012; Brito et al., 2016, 2018; Ward, 2016). In general, the naturally stressed biota and water scarcity that characterize the desert biome poses environmental challenges to sustainable human development and natural resource use. Deserts do not regenerate quickly and human impacts can remain in this biome for decades. The combined pressures of exerted by urbanization and traffic, farming and overgrazing, water overexploitation and salinization, and natural resource extraction, is leading to the degradation of world's deserts (UNEP, 2006; Ward, 2016), with the addition that these are deprived of the native biodiversity.

The nomadic lifestyle was the only way humans had to survive in deserts for centuries. Housing and urban development are relatively recent and expanding processes in deserts, and are threatening habitats and unique vegetation communities. For instance, biodiversity decline in the coastal areas of the Arabian Peninsula is linked to development and urbanization, as well as to overexploitation of natural resources, both resulting from growing human population and lifestyle changes (Tourenq and Launay, 2008). Off-road recreational vehicles particularly impact the fragile arid areas, by soil compaction, accelerating water and wind erosion, vegetation destruction, or by the effect of vehicle noise on desert vertebrates (UNEP, 2006).

Farmland surface has increased dramatically in some deserts, causing habitat loss and fragmentation, and groundwater over-exploitation. These processes affected large portions of coastal areas of the Arabian Peninsula or the African Sahel. Grazing is a major

Table 1 Examples of convergent evolution in four world deserts

Guild	North America	Australia	North Africa	South Africa
Succulent plants	Cactacea <i>Yucca</i>		Euphorbiaceae	Euphorbiaceae <i>Aloe</i>

Despite these taxa have different phylogenetic origins and biogeographic histories, many share strikingly similar morphological traits.

Adapted and expanded from UNEP (2006). *Global deserts outlook*, Ezcurra, E. (ed.) Kenya: United Nations Environment Programme. <http://www.unep.org/geo/gdoutlook/> and Ward, D. (2016). *The biology of deserts* (2nd edn). Oxford: Oxford University Press.

cause of land degradation across the desert biome, especially at its margins. For example, excess of pastoral activity affected the threatened populations of Houbara Bustard, *Chlamydotis undulata*, in the north-western fringe of the Sahara, and cattle grazing and browsing have damaged sensitive desert scrubs and riparian habitats in the Chihuahuan Desert in Mexico (UNEP, 2006). Water overexploitation for human and livestock consumption threatens local fauna and flora (Fig. 8). For instance, fecal pollution, eutrophication and water shortage during the dry season are linked to increased pressure over fragile crocodile populations scattered in isolated mountains of the Sahara-Sahel (Brito et al., 2014). The extraordinary micro-endemism levels of the desert springs fed by the Australian GAB are threatened by groundwater use, with extraction partially exceeding recharge rates and drastically degrading the groundwater dependent ecosystem (Murphy et al., 2013). In the north-western margin of the Sahara, numerous water cisterns were built for watering livestock, which attract desert vertebrates (mainly reptiles and mammals) and act as unintentional death traps for them and changes the variety and quality of amphibian breeding sites, causing additional pressures over already scattered populations in desert habitats (García-Cardenete et al., 2014).

The exploitation of natural resources is growing across world's deserts, through industrial mining, oil and gas exploration, and recently by photovoltaic and wind power stations, and it is threatening the locally fragmented and remnant desert biodiversity. For example, the highest mountain system in Mauritania (Kediet ej Jill) and the surrounding rock outcrops are partially falling apart by the intense iron ore extraction, even before these habitats are scientifically explored. The projected growth in natural resources exploitation in world's deserts is likely to further threaten biodiversity. For instance, prospection for new oil sources in Niger was the major reason for population collapse of critically endangered Addax, *Addax nasomaculatus* (Fig. 8; Durant et al., 2014), and increasing mining activities in the Central Basin desert of Iran further threatens the last wild populations of the Asiatic cheetah, *Acinonyx jubatus venaticus* (Khalatbari et al., 2017).

Accessibility to world's deserts is growing and linear infrastructures are an increasingly common feature in most desert landscapes, mostly through roads but also by railways and pipelines. These features threaten local biodiversity by increasing vehicle-collision probability, modifying animal behavior, and by allowing the spreading of invasive species and the increasing human use of previously remote areas. For example, road collision is currently one of the most important threats to the critically small Asiatic cheetah populations in Iran (Khalatbari et al., 2017). The expansion of road networks and also the growing usage of

Fig. 8 Examples of threats in desert biomes. (A) Oil exploration, Niger; (B) fecal pollution and eutrophication of mountain rock pool, Mauritania; (C) overhunting and biological resource use, Mauritania; (D) increasing road network, Mauritania. Photograph credits: José C. Brito.

four-wheel-drive vehicles is increasing the accessibility to previously remote areas in most world deserts, which combined with the spreading of firearms, is amplifying the impacts of overhunting (Fig. 8). The negative synergistic combination of these factors has been associated with the decline in threatened fauna of the Sahara-Sahel, particularly in large body-sized vertebrates (Durant et al., 2014; Brito et al., 2018), a pattern also observed in the Arabian desert (Tourenq and Launay, 2008). The recent increase in global conflicts, particularly in deserts and arid regions, is further threatening already imperiled fauna. Within the Sahara-Sahel countries, the absolute number of conflicts has growth 565% over the last 20 years, and this trend was associated with the decline and in some cases with the massacre of large mammals, including the Addax, the Dorcas gazelle, *Gazella dorcas*, and the African savannah elephant, *Loxodonta africana* (Bruto et al., 2018).

Climate change will increase extinction rates of organisms in the future and is projected to be more severe in deserts in comparison to other biomes. Deserts experienced an overall increase in temperature of 0.5–2°C between 1976 and 2000, a much higher value than the average global temperature increase (0.45°C), which has been attributed to the higher atmospheric concentrations of greenhouse gases (UNEP, 2006). Current and future climate warming would affect the phenology and distribution of many species, and in synergistic combination with other human-induced threats in the desert biome, will probably lead to range contraction and species extinction. Given that desert-adapted species already live close to their physiological limits, they may be the most vulnerable ones, as suggested for the endemic vertebrates of the Sahara-Sahel (Vale and Brito, 2015). Ecological niche-based models projecting biodiversity distribution under climate-change scenarios predict dramatic losses of suitable climates with potential consequences in species diversity. For example, the Tassili n'Ajjer National Park of Algeria is predicted to lose about 50% of current mammal richness, with only about 10% species gain (reviewed in Brito et al., 2014). Climate warming may also favor range expansion of invasive organisms sensitive to low winter temperatures, as observed in invasive Neotropical plants in the North American deserts.

Biodiversity Conservation in Desert Biomes

Still there are good reasons for hope because most world deserts are among the last wilderness areas at global level that can still be considered mostly intact (UNEP, 2006; Davies et al., 2012), and where implementing conservation actions would be most cost-effective. Because of climatic constraints, more than the 90% of the tropical deserts of the world remain uncultivated, has rather low economic value, and the protection of these areas for biodiversity conservation is rather inexpensive (Durant et al., 2014). Area prioritization for biodiversity conservation begin to be available for some deserts organisms, such as the continental vertebrates of the Sahara-Sahel (Bruto et al., 2016), but these efforts needs to be extended to regional/national scales and for other world deserts. Reserve design targeting desert freshwater diversity needs to consider the effects of hydrology and species' ecology on population connectivity (Murphy et al., 2015b). The assessment of the conservation status under the IUCN Red List criteria is still poorly developed in desert-dwelling species, and needs to be extended to regional/national scales and for invertebrates in particular (Rossini et al., 2018).

The percentage of deserts and drylands that are formally designated as protected areas is gradually increasing, but the protected area coverage is below the 10% target of the Convention on Biological Biodiversity (UNEP, 2006; Davies et al., 2012). For instance, Niger declared the largest reserve of Africa for the protection of the Addax population, but local biodiversity hotspots with high endemism rates associated with rare perennial wetlands remain mostly unprotected, as are the cases of the mountains rock pools of Mauritania and the desert springs of the Australian GAB (Vale et al., 2015; Rossini et al., 2018). Deserts extending over developing countries, such as in the Sahara-Sahel, currently lack the resources and capacities and in some cases the commitment to make the strong structural changes needed to ensure sustainable natural resource management and social stability (Bruto et al., 2018). Changing the current status of poor governance, high corruption levels, low income, and lack of perspectives on social development and poor human rights enforcement that characterizes Sahara-Sahel countries remains a major societal challenge.

At the local scale, Community-based Natural Resource Management projects are building awareness of the environment and the cultural, economic and ecological importance of biodiversity and ecosystem services, as in the cases of the high Andes of Peru, Namibe desert or the Mongolian Gobi desert (Davies et al., 2012); these efforts need to be extended to other world's deserts. Actions directed at improving education and awareness on the local biodiversity can be a rewarding path to enhance desert conservation. Local communities have a good perception of the surrounding biodiversity, and stimulating collaboration with researchers, environmental managers and ecotourism agencies may be of cultural benefit for them, generate alternative income sources, and improve their understanding of the ecosystem services afforded by deserts (UNEP, 2006; Brito et al., 2014). Responsible ecotourism-based industry may provide alternative and better livelihoods to the local people, and is one of the ecosystem services provided by deserts that still remains unexplored.

Conservation actions directed at managing or restoring threatened populations of regionally extinct or threatened species are occurring in the world's deserts. For example, extensive conservation efforts were developed to save the two remaining natural populations of the Numbat, *Myrmecobius fasciatus*, in Australia, while conservation breeding and reintroduction programs have succeeded in establishing six populations in its former range (Davies et al., 2012). In Chad, concerted actions between local administrations, the environmental authorities of Abu-Dhabi, and the Sahara Conservation Fund (www.saharaconservation.org) allowed the recent reintroduction of the Scimitar oryx, *Oryx dammah*, in the Ouadi Rimé-Ouadi Achim Game Reserve, after decades of being considered extinct in the wild. Morocco is developing an ex situ breeding facility (M'cissi Reserve) of large ungulates (Oryx, Addax) and the Ostrich, *Struthio camelus*, to be reintroduced in the northwestern fringes of the Sahara, while captive breeding and

releasing programs of Houbara Bustard are being successful, although they are aimed at maintaining hunting activities, by falconry, on this large bird (UNEP, 2006). Reintroduction and restocking of wild species is a first step for the restoration of ecosystem function in deserts (Durant et al., 2014), but such operations require detailed decision processes and are costly, lengthy and logistically difficult, reinforcing that local extinction should be avoided whenever possible (Brito et al., 2018).

Management actions directed at conserving threatened species or restoring sites are developing across the world's deserts. Measures are being developed to reduce the accidental entrapment of desert organism in anthropogenic infrastructures by on-site, cost-effective management actions, such as the case of roadside fencing and animal underpasses forecasted for the Semnan-Mashhad highway (N44), stretching along the northern boundary of Touran Biosphere Reserve in Iran, where road collision is a major cause for population decline in Asiatic cheetah (Khalatbari et al., 2017). Dense wire mesh in the inlet and overflow slits of the modern water cisterns for watering livestock could prevent wild desert organisms from being caught, and simple ramps in the settling tanks could facilitate the escape of trapped species, while not restricting livestock from watering. For example, in the north-western fringe of the Sahara, this mitigation measure reduced 66% of amphibian and reptile mortality from trapping (Pleguezuelos et al., 2017). However, the management of desert spring in North America and Central Australia must include disturbance produced by livestock to maintain the native fish fauna, probably because a long history of disturbances by native mammals and aboriginal humans in these habitats.

Molecular-based studies are unraveling cryptic diversity and geographic structuring in genetic diversity across the world's deserts that should be preserved. For example, conservation of the threatened Cuvier's gazelle, *Gazella cuvieri*, in the northern Sahara should consider the preservation of the recent mountain and lowland ecotypes to maintain the overall adaptive potential of the species (Silva et al., 2017). In the desert springs of the Australian GAB, molecular studies have uncovered massive numbers of endemic forms in aquatic invertebrates (Murphy et al., 2013). The systematic status of these genetic demes and the evolutionary drivers of such diversity are mostly unknown (Brito et al., 2014). Molecular studies will likely continue to reveal additional biodiversity in the desert biome.

Long-term conservation of desert biodiversity requires appropriate policy instruments that promote conservation and sustainable use of natural resources. Strong commitments for change in global attitude towards nature and biodiversity conservation and regional stability are needed to drive societal change. Raising environmental alertness and pride within local communities of the value and uniqueness of the desert wildlife is needed to pressure strong policy change (Brito et al., 2018).

Abstract

The global arid lands, or drylands, can be loosely-defined in terms of precipitation and evapo-transpiration, which characteristically result in semi-permanent water scarcity. This manifests itself in low soil moisture availability, ephemeral stream and river flow, and a plant cover that occupies only a part of the landscape. However, microphytic plants occupy many areas of otherwise bare soil where vascular plants are absent, and can confer some resistance to wind and water erosion. Dryland plants have developed some important adaptations to water scarcity, including the ability to capture rain and deliver it as stemflow to the soil around the base of the plant. There are also community-level adaptations that permit more abundant vegetation cover than might be expected in water-scarce environments. These include various kind of patchy vegetation, in which water is shed from bare areas and drains downslope to support localized groves of plants. A striking form of this adaptation that occurs in many parts of the global drylands is known as “tiger bush.” Drylands face ecohydrological change as global and regional climates change. A key issue that remains to be fully resolved is the extent to which dryland ecosystems are vulnerable to the effects of such change. In some ways that are discussed in this article, drylands may be seen as possessing some attributes that may in fact make them somewhat resilient to climate change.

Introduction

Drylands may be distinguished from other environments, landscapes, and ecosystems using a range of criteria. There can be no single definition of a dryland, owing to the great diversity of global dryland regions, some of which are dominated by sand, others by rock; some are semiarid whilst others are hyper-arid; some are fire-prone; many are affected to varying degrees by human occupation, resource extraction, or by the introduction of grazing or pest organisms (Canadell et al., 2007).

Dryland landscapes owe much of their fundamental character to water scarcity arising from a range of causes. Rock type may exacerbate aridity, as in karstic regions where rock solubility allows precipitation to pass into the deep groundwater relatively rapidly, leaving the surface dry as a “lithological desert.” Shallow soils, with limited capacity to store water between falls of rain, can locally also contribute to water scarcity and can increase the difficulty of sustaining plant growth. This effect is not distinctive of drylands, however, since even in humid areas, shallow soils can result in plant moisture stress akin to that occurring in deserts, if rainfall is low for an extended period and evapotranspirative demand is high.

Unsurprisingly, therefore, definitions of drylands by different authors are based on differing sets of “defining characteristics”; however, because of the essential character of water scarcity, most of these rely on one or more aspects of climate or hydrology that are considered to be distinctive of deserts. These include the idea that deserts are areas of “low and highly variable precipitation of generally small event sizes and particularly vulnerable to climate change” (Palmquist et al., 2016), or “regions with relatively low precipitation, long dry spells and frequent occurrence of water scarce conditions” (Wang et al., 2011), or areas characterized by “potential rates of ET greatly exceeding rainfall input” (Jenerette et al., 2012). D’Odorico and Porporato (2006) noted that “Drylands are drought-prone areas of the world in which rainfall is less than the potential evapotranspiration for the whole year or for part of it, and conditions of either permanent or seasonal soil water deficit occur. The obvious features of the rainfall regime are the low precipitation amounts and the high variability and unpredictability of precipitation, which occurs in a discrete number

of relatively infrequent events.” Thus, dryland ecosystems are in general water-controlled “with infrequent, discrete, and largely unpredictable water inputs” (Noy-Meir, 1973, 26).

From these few definitions, selected from a large number that have been used, we can assemble a list of proposed ecohydrologic characteristics of drylands:

- low and highly variable precipitation
- unpredictable precipitation
- small rainfall event sizes (depths)
- relatively infrequent rainfall events
- long dry spells with water-scarce conditions
- potential ET greatly exceeding rainfall input
- drought-prone
- permanent or seasonal soil water deficit
- vulnerable to climate change

Most of these proposed characteristics relate to the low and variable dryland rainfall, together with the resulting scarcity of soil moisture. However, as will be considered below, a knowledge of dryland rainfall is only the first step in understanding the availability of water to organisms and the occurrence of important ecosystem processes such as overland flow on dryland hillslopes and the ephemeral flow in desert streams and rivers. Many components of dryland landscapes and ecosystems affect both the distribution and availability of water that cannot be understood from a knowledge of the rainfall alone. For instance, desert trees, shrubs and grasses, and even microphytic plants, commonly exert an influence on hydrologic processes including interception and the partitioning of rainfall before water finally reaches the soil. Moreover, as we shall see, nonrainfall water can be vital in some drylands, where fog and dew become as ecologically-important as rainfall. Their occurrence may also be far more regular and predictable than dryland rainfall. The reader is referred to D’Odorico and Porporato (2006) for an account of dryland ecohydrology and to Nicholson (2011) for a general review of the climatology of dryland regions.

Why Are Drylands and Their Ecohydrology Globally Important?

Drylands are variously assessed as covering 30%–>40% of the global ice-free landsurface and therefore occupy a sufficiently large area to exert an influence on the continental albedo, landsurface temperatures, runoff from large regional drainage basins, chemical and physical weathering rates, and other components of the global land-atmosphere system. Low erosion rates in drylands (Perron, 2017) in turn affect regional tectonics, and hence, there is a feedback from tectonics to regional climate. Ahlström et al. (2015) investigated the importance of carbon sequestration or release in the globally extensive dryland ecosystems to fluctuations in the atmospheric CO₂ concentration. Whilst tropical forests dominate the global biomass sink for carbon, the semi-arid lands in the model of Ahlström et al. (2015) accounted for most (0.04 Pg C a⁻¹) of the time trend in net biome production (several Pg C per annum). They speculated that this was attributable to the encroachment of woody plants in semi-arid areas, reflected in the increased greening observed in satellite data. In the drylands of the Southwestern United States Brunelle et al. (2013) confirmed this trend, and observed that it paralleled the rising concentration of atmospheric CO₂ that unhelpfully for the confident attribution of causes, occurred concurrently with a period of intensification of grazing. D’Odorico et al. (2010) have shown that there can be a positive feedback between shrub growth (in *Larrea tridentata*) and microclimatic conditions that favor shrub growth, including a rise in minimum winter temperatures. In this way, relatively small changes in the external climate might result in significant ecosystem shifts, via regenerative change (positive feedback).

In many drylands, plant cover occurs in patches rather than as a continuous cover. It is hypothesized that this is a potentially metastable intermediate state between the full vegetation cover of humid regions and the virtually complete absence of vascular plant cover of the most hyper-arid regions. As a corollary, it is thought that landuse and climate change pose a risk of regime change or “catastrophic shifts,” involving a possible collapse of plant cover to bare desert. If this is so, then the drylands may be important to regional hydrology and influence regional and perhaps global climate, since vegetation is important to the hydrologic cycle interactions of the landsurface and the atmosphere. Using a coupled atmosphere-biosphere model, Snyder et al. (2004) explored this by removing in turn the vegetation cover in major biomes globally (including the tropical and boreal forests, temperate forests, savanna, and shrubland). Results showed varying effects on rainfall and temperature. Removal of the tropical forest vegetation reduced rainfall by 1.3 mm d⁻¹ (24%) over the entire biome. Loss of dry shrublands in Australia resulted in temperature increasing by 1.2°C in summer, and cooling by a slightly smaller amount in winter. Rainfall over much of dryland Australia also declined by 1–2 mm d⁻¹, attributed to lower concentrations of water vapor in the atmosphere, owing to the reduced moisture flux from plant transpiration. Findings such as these emphasize that rainfall in the drylands as elsewhere, is not solely an atmospheric phenomenon, but shows a strong dependence on the landsurface, and the extent to which vegetation there recycles and transpires moisture. Condensation of transpired water vapor in the atmosphere releases the latent heat of vaporization, and this is an important driver of convection within the atmosphere. The partitioning of solar radiation into sensible heat (H) and latent heat (LE) affects the strength of atmospheric uplift, the formation of cloud, and hence rainfall. Bare surfaces can exhibit a high albedo, which leaves a reduced net radiation at the surface, and a smaller capacity to warm the lower atmosphere and drive the convection that gives rise to rainfall.

There are many other ways in which the condition of the global drylands and their vegetation are linked to components of the broader Earth-system. One is via the transfer of dryland dust to the oceans, where the iron contained in the dust enhances the productivity of marine phytoplankton, which normally suffer iron limitation. The flux of dust is itself linked in part to the occurrence of drought, and decline in plant cover, in the drylands. The effects of the dust have global climate ramifications (Jickells et al., 2005), and, by forming overly-numerous condensation nuclei, may result in the inhibition of rainfall. Further consideration of the global dust flux from drylands and its environmental role is beyond the scope of this chapter, and is not considered further.

It is worth briefly recalling how the global drylands are involved in the inter-connected tectonics—erosion rates—climate interactions. Orogenic uplands may result in aridity downwind (the rainshadow effect), as exhibited in the Tibetan Plateau or the South American Altiplano. The dryness of these areas reduces river flows and erosion rates, and limits the ability of rivers to maintain their course across the rising uplands. Basins of internal drainage may result, such that sediment is not unloaded from the crust to allow ongoing uplift, but rather accumulates. This then feeds back to rates and mechanisms of orogenesis (Strecker et al., 2007), and to the occurrence of areas of higher rainfall related to orography.

Owing to its evident pivotal role, let us consider the nature of dryland rainfall in a little more detail.

Rainfall in Drylands

Rainfall in drylands, as in all environments, occurs in episodes—rainfall events—separated by rainless periods. Rainfall events in many climatic environments may be brief, lasting perhaps an hour or a few hours, or may extend over several days. Consequently, the tallying of daily rainfall amounts as a means of exploring the differences among, say, wet tropical and dryland rainfall climatologies, may not offer sufficient temporal resolution to explore the argument raised earlier that dryland rainfall is characteristically brief in occurrence. Many overviews of dryland rainfall consider primarily annual and seasonal amounts, and perhaps the kinds of intensities that occur (e.g. Williams and Lazarides, 1985). However, the arrival of rainfall over minutes to hours is especially important in the ecohydrology of drylands, because at other times, high evaporation rates mean that soils become dry and surface water does not occur.

Are the characteristics of rainfall events more critical to dryland ecohydrological processes than in other climates and biomes? Almost certainly, the answer is “yes.” Small amounts of rain are vulnerable to rapid evaporative loss following the rain, and therefore to generate important landscape-scale outcomes such as recharge to the groundwater system, or to cause desert streams to flow, commonly requires large events—at least tens of mm. Recharge may occur from the flow carried by river channels, especially through porous, sandy and gravelly channel sediments that are normally dry, or through the floors of desert lakes and playas (Fig. 1). Because the channels of dryland rivers are normally dry, there can be high rates of transmission loss—reaching 5%–10% discharge loss per km of flow—into the channel-margin sediments as the empty intergranular pore spaces there are filled. As a result, river flows may not arrive at the playas or other basins toward which they drain, except in large events that carry sufficient volume to survive the transmission losses. In humid climates, where there is often a permanent baseflow sustaining perennial streams, many of these processes do not occur; across whole landscapes, groundwater recharge frequently amounts to hundreds of mm a^{-1} . In drylands, sufficiently large rainfall events to cause river flow or groundwater recharge are uncommon, and rates of groundwater recharge are typically $< 1\text{--}2 \text{ mm a}^{-1}$, or perhaps just 1% of the rate seen in humid environments. In many dryland areas, recharge rates are lower still, at $\sim 0.1 \text{ mm a}^{-1}$. Large rainfall events are important to biological outcomes, also; they may be required in order to generate overbank flows capable

Fig. 1 The dry sandy bed of an ephemeral drylands stream (Fowlers Creek, western New South Wales, Australia). During the brief flows in this stream, water infiltrates into the bed and banks, later supporting the trees lining the channel during the long periods when it remains dry.

of supporting seedling establishment and tree growth along river corridors; they may also be associated with major episodes of flowering and seed production, and of breeding cycles of fish, birds, and amphibians along rivers and in ephemeral lakes. In turn, especially in semi-arid areas, vegetation may influence groundwater recharge, via soil macroporosity, concentrated stemflow, and other mechanisms. More recharge appears to occur beneath the trees of dry woodlands than in the open spaces between trees (Ilstedt et al., 2016). Ecologically-important ephemeral pools may be left in ephemeral stream channels once the flow has ceased, especially where the bed is locally rocky or less permeable than elsewhere. If shaded by overhanging trees, these pools can in some cases persist for week or months (Fig. 2).

It is useful in seeking to characterize rainfall events and their temporal characteristics, to adopt a formal definition of a rainfall event. This is most often done by defining a “minimum inter-event time” (MIT), the minimum number of rainless hours that must occur in order for subsequent rainfall to be identified as a new rainfall event. A wide range of MIT values has been used in published literature, ranging from 15 min to 24 h (Dunkerley, 2008); however, a value of 6 h is common, and is frequently adopted because it corresponds to the length of time needed for plant foliage to become dry after a rainfall event. The use of the MIT approach to delimit rainfall events means that long events can contain periods when rain ceases temporarily, but these cannot exceed the MIT, or else a new event is identified. Importantly for dryland rainfall, events can have durations of just a few minutes or tens of minutes, and they can begin and end at any time. Thus, a 17-min rainfall event might begin at 16:55 and end at 17:12. This makes the statistical properties of rainfall events more useful in describing brief showers than aggregated daily or hourly totals.

Are desert rainfall events distinct from those of wetter areas? Barbosa et al. (2018) examined rainfall events delineated using the MIT approach at hot semiarid and tropical wet climates in north-east Brazil. Their results are summarized in Table 1. The semiarid locations have longer, larger and more intense rainfall events than the wet tropical site.

The results from Brazil suggest that at the semiarid locations, rainfall events are larger, longer, and more intense than at the wet tropical location. The values change slightly if a different statistical measure is used, such as the median rather than the mean. In light of this, taken together with the smaller mean annual rainfalls at the semi-arid locations, it is evident that the annual rainfall could be delivered in a smaller total time there than at the wet tropical site. Using just the mean figures as an approximation, the rain durations (annual total/mean intensity) would be 48 h at Aiuaba, 48.5 h at São João do Cariri (both about 2 days), and 200.2 h at Guaraíra (more than 8 days). The data show how short the mean rainfall event is—only about an hour at all three locations.

In a similar study, Dunkerley (2018) compared rainfall events at Broken Hill, New South Wales, in the Australian drylands, with Millaa Millaa in the wet tropics of far northern Queensland, Australia (Table 2).

The results differed from those for Brazil (Table 1) except that the dryland site, as in Brazil, exhibited more intense rainfall events than the wet tropical site. Using the mean figures as before, at Broken Hill if rain fell at the mean event intensity, it would require 51 h to deliver the mean annual rainfall. At Millaa Millaa, this would take 1126 h (about 47 days). Again it is evident that the duration of rain is relatively brief at the dryland locations. These very approximate estimates can be compared with the actual figures for the total time occupied by rainfall events, which are on average 141 h a^{-1} (Fowlers Gap) and 2426 h a^{-1} (Millaa Millaa), so that mean annual aggregate rainfall event duration is on average more than $17 \times$ larger at wet tropical Millaa Millaa, than at the dryland site, Fowlers Gap.

To the descriptors of the rainfall climatology of deserts referred to previously, we could add the nature of the “rainfall event intensity profile”—that is, the pattern of rainfall intensity fluctuations during the course of the rainfall event, including any periods when the rainfall ceases temporarily. The intensity profile has been relatively neglected in studies of dryland rainfall climatology, but it is

Fig. 2 This pool of water accumulates in a low-lying section of the channel of an ephemeral stream that is normally dry (Fowlers Creek, western New South Wales, Australia). It is slowly lost to seepage and evaporation, but is an important water source for the trees lining the channel, as well as for local fauna.

Table 1 Rainfall at three locations in Brazil

<i>Rainfall characteristic</i>	<i>Aiuaba</i>	<i>São João do Cariri</i>	<i>Guaraíra</i>
Mean annual rainfall (mm)	560	460	1700
Mean event duration (h)	1.2	1.0	0.9
Mean event depth (mm)	10.8	8.38	5.95
Mean event rainfall rate (mm h ⁻¹)	11.64	9.49	8.49

Table 2 Rainfall at a dryland location and a wet tropical location in Australia

<i>Rainfall characteristic</i>	<i>Broken Hill, dryland NSW</i>	<i>Millaa Millaa, wet tropical Queensland</i>
Mean annual rainfall (mm)	~220	~2500
Mean event duration (h)	5.1	18.6
Mean event depth (mm)	10.2	21.3
Mean event rainfall rate (mm h ⁻¹)	4.3	2.22

important for several reasons. First, even if rain is continuous during an event, the intensity is likely to fluctuate, and the position of periods of intense rain in the course of the event affects the partitioning of the rainfall among surface ponding, infiltration, and overland flow (Dunkerley 2012). If, for instance, the most intense rain comes late in an event, then the soil surface will already have become wet, and a larger amount of the rain may be partitioned into overland flow. If the intense rain arrives early, before the soil has become wet, more of the rain may infiltrate. If rain ceases briefly during an event, then any surface ponding has a chance to infiltrate, renewing the depression storage capacity; likewise, plant foliage has a chance to dry, renewing the canopy interception storage capacity. In the water-scarce drylands, all of these effects are worthy of study and almost certainly have ecohydrological importance.

The analysis and description of temporal profiles is not yet standardized. Todisco (2014) for instance identified “first half storms” and “second half storms,” and found that for Masse (central Italy), “first half storms” dominated. Early analyses of temporal profiles divided storm durations into four equal-length segments, called “quartiles.”

What forms of intensity profile are found in drylands, as compared with, say, wet tropical locations? Where convective rain is important, driven by heat-driven uplift from hot soil surfaces in the late afternoon, early intensity peaks (first-quartile storms) would be expected. Once intense convective rain has commenced, the soil surface is rapidly cooled evaporatively, and the uplift and convergence of moist air is slowed; in this way, the intensity declines toward the later phases of a convective rainfall event. In nondesert environments, frontal, monsoonal, or orographic rain would not be expected to follow the same intensity profile. For Brazil, Barbosa et al. (2018) found largely constant intensity (“rectangular” event profile) for their wet coastal site. In contrast, Aiuaba, a semi-arid inland site, showed mostly early-peak (their “unimodal left-skewed” type). Dunkerley (2013) analyzed event profiles for dry and wet years at Fowlers Gap in dryland NSW, where there are large inter-annual fluctuations in rainfall linked to ENSO. He showed that in wet years, first quartile events were the most common, but that the largest share of the total rainfall was delivered in third quartile events. In contrast, in dry years the largest proportions of both events and rainfall were in first quartile events. This is potentially ecologically important, since first quartile events tend to promote infiltration, and so reduce moisture stress in dry years. Full details of rainfall event profiles, and their ecological significance, remain unexplored for many global drylands.

Interannual Variability in Rainfall, Including Drought, in Drylands

Marked variability in rainfall is a widely-cited characteristic of drylands; rain may occur with marked intermittency, and with long dry spells between falls. These dry spells may last for weeks to months; for Fowlers Gap, Dunkerley (2008) reported a mean waiting time between rainfall events (MIT = 6 h) of 83 h, but the longest dry spell extended for 2443 h (about 102 days).

Years of well below average rainfall, especially multiple successive years, may result in severe droughts in drylands. During drought conditions, soil moisture can fall to levels that cause mortality in plants, including long-lived taxa such as trees and woody shrubs. As a result of drought, vegetation cover may decline, and wind erosion can become dominant. In drought conditions in arid western NSW, the author has observed that abrasion by saltating sand can erode the biological soil crusts that help to stabilize silty soils against wind and water erosion, so exacerbating the effects of the drought. The rainfall record for the regional city of Broken Hill provides quantitative examples of the variation in annual rainfalls. In 1902 (a year included in the Federation drought of 1895–1902; Ummenhofer et al., 2009) Broken Hill recorded rainfall of 91 mm. In 1940, during the “World War II” drought, the yearly rainfall at Broken Hill fell to 57.4 mm, or just 22% of the long-term average annual rainfall at the Patton Street raingauge station, which is 260 mm (based on 122 years of record, 1889–2015). The wettest year, 1974 (838 mm) was nearly 15 × wetter than 1940. The coefficient of variation (CV) of the annual rainfall for this station is 0.45; for Australian dryland rainfall stations in the Lake Eyre Basin, McMahon et al. (2008) reported a maximum CV of 0.79 at Mungeranie. Overall, the CV was found to be ~60% larger than for other global dryland regions, in part related to the influence of ENSO. In even more arid locations, the CV may lie in the range 1–2, or even larger, and completely rainless years or runs of years may occur.

Taking a Longer-Term View of Dryland Rainfall

Historical, instrumental rainfall data only span a short period—perhaps 100 years in many cases, and often less. They can consequently not represent conditions through even millennial timescales, and it is well established that past climatic and hydrologic conditions are not the same as conditions experienced in the last 100 years or so. For instance, as noted above, parts of the Australian drylands have experienced several severe droughts in the 20th and early 21st centuries. However, instrumental records only began in Australia in the mid- to late-19th century, and it is therefore unclear whether the historical droughts were more or less severe, or long-lasting, than droughts of prior centuries. Various proxy records can be used in an attempt to extend the rainfall record and detect wet and dry periods prior to instrumental records.

Some recent examples illustrate this. Lough (2011) recorded luminescence in *Porites* corals from the Great Barrier Reef off the east coast of Australia, where coral growth is affected by major freshwater floods; this is recorded in the growth bands of the coral. The coral record was correlated with instrumental records and the relationship was then extended to earlier dates. Results showed details of rainfall from the late 1600s, including an extended drier period from the 1760s to 1850s, when interannual rainfall variability was reduced. Vance et al. (2015) examined ice core evidence from the Law Dome in East Antarctica, with dating done by layer counting. Accumulation rates of snow, and sea salt abundance in the ice, were recorded, and correlated with climatic conditions in Australia. Results suggested the occurrence of 8 Australian “megadroughts” lasting more than 5 years, including one drought which lasted for 39 years in the period 1174–1212 CE. The 12th century was found to be a long period of unprecedented dryness.

Results such as these, though relying on indirect proxy evidence, and attended by the challenges of calibration and verification, nonetheless suggest strongly that the variability of dryland rainfall known from the historic period does not reflect conditions through recent geological time. In particular, the occurrence of longer droughts than have occurred historically is a striking suggestion from the proxy studies. Future climate change may bring more frequent or more geographically-widespread droughts. In various parts of the world, rainfall exclusion experiments, using roofing placed temporarily above shrublands and other dryland vegetation communities, is being used to build an understanding of the possible effects of future droughts (e.g. Longepierre et al., 2014).

The Fate of Rainfall Near the Groundsurface: Canopy and Litter Interception and Stemflow

Rainfall in drylands may in large part arrive at the surface of bare soil, rock, sand, or alluvium (Fig. 3). However, even where the soil lacks vascular plant cover, rain may make first contact with microphytic plants such as lichens or mosses; cyanobacteria also colonize many dryland soil surfaces. These may cover extensive areas of soil and rock, and are generally referred to as “biological soil crusts” (Fig. 4). Where vascular plants—grasses, shrubs, and trees—are present, rainfall may initially contact the foliage, branches and stems of the plants, or else fallen organic litter of leaves, twigs, flower parts resting on the ground (Fig. 5). In all these situations, water is partly intercepted before it can reach the soil. From the interception stores it may be absorbed, evaporate, or splash, drip, or trickle down the plant to reach the soil as released throughfall or stemflow (also referred to as contact flow). Water may be lost to evaporation from the interception stores, even during rainfall, at rates of perhaps 0.4 mm h^{-1} , which is significant in relation to the common dryland rainfall intensities of just a few mm h^{-1} .

Experimental studies of dryland plants have investigated the amount of water intercepted or delivered to the base of a plant as stemflow. In China, stemflow in *Caragana korshinskii* amounted to 8% of the rainfall on average, and was delivered after a minimum

Fig. 3 A typical arid landscape in the drylands of Australia. Here, rocky ridges carry relatively little vegetation owing to their thin, stony soils. In contrast, on different lithologies in the valley, trees are able to survive, aided by runoff from the rocky hillslopes.

Fig. 4 A cyanobacteria crust that has colonized the surface of a loamy dryland soil. The image shows the typical structure of separate plates in the crust. In the foreground, the crust, which normally confers some erosion resistance to the soil, is being broken up and eroded, perhaps as a result of grazing stock.

Fig. 5 Scattered trees in the Australian drylands, showing the way in which such plants may alter their local micro-environment. The soil beneath each tree benefits from some shade, and the patches of litter visible in the photo increase the availability of soil organic matter. These favorable locations also support more abundant soil and decomposer organisms, and typically have higher infiltrability. Note that soil between the trees is largely devoid of vegetation.

of 2.2 mm of rain. [Yuan et al. \(2017\)](#) presented a lower estimate of 0.9 mm for this shrub, and a slightly higher value of 2.1 mm for *Salix psammophila*. Inter-specific differences relate to properties of the foliage and stems, including the architecture and inclination of the branches. The focused delivery of stemflow, with funneling ratios of up to ~ 90 , was found by Yang et al. to recharge relatively deep soil moisture. [Slatyer \(1959\)](#) reported that mulga trees (*Acacia aneura*) in central Australia also shed stemflow after as little as 2–3 mm of rain, and in many storms delivered about 40% of the rainfall over the projected canopy area. He stressed that the 100 L or so of stemflow delivered to the base of a tree in a rainfall of 15–20 mm amounted to an important water source for the plant in the dryland conditions of inland Australia. Working on mulga in south-west Queensland, [Pressland \(1973\)](#) found that 18% of gross precipitation was channeled as stemflow, though the proportion declined slightly in events of > 10 mm. This decline was attributed to an increase in stem and leaf drip, resulting in reduced contact flow. [Pressland \(1976\)](#) drew additional attention to the fate of the stemflow, noting that it had been observed to infiltrate within 50 cm of large trees, and 30 cm of small trees. In this way, he showed that the increase in effective depth of precipitation over the area around the base of the plants, where the stemflow is concentrated and within which it is absorbed, reached almost 200% of the open-field rainfall for a 10 mm rainfall over a small tree. Though very few plant taxa have been studied, the available evidence suggests that in drylands where many rainfall events are small, the funneling of stemflow boosts the delivery of water to the base of the plant, and supports deeper penetration of the wetting front in the soil beneath the plant. There, the stored water is available to support the plant during the potentially long waiting time until the next rain.

[Magliano et al. \(2019\)](#) present an overview of interception, throughfall and stemflow in the global drylands.

Fog and Dew in Drylands

The nocturnal cooling of the ground surface that occurs under the frequent clear-sky conditions of drylands is conducive to the formation of dew. Dry uplands adjoining warm oceans may be exposed to drifting fog and mist, or low cloud, from which plants may extract moisture. Dew and fog water are both forms of occult precipitation, and their ecological role, which has been studied in a number of drylands, is locally important. The water can be directly absorbed into the leaves of some plants, without having to enter the soil, and also supports biological soil crust organisms. Cacti of the American deserts accumulate dew, assisted by their spines. In the Negev, Hill et al. (2015) used environmental isotopes to establish that three taxa, *Salsola inermis*, *Artemisia sieberi* and *Haloxylon scoparium*, derived 56%, 63% and 46% of their water from dewfall, and concluded that dew was an important aid to plant survival in the water-scarce Negev. Soil may also take in water directly, by absorption, from the humidity of the lower atmosphere. Though this water may not be used by plants, it nonetheless become involved in evaporation, and hence in the overall energy balance and temperature regulation of the dryland surface. In addition to supporting plants, water absorbed from the atmosphere may facilitate microbial activity in the soil, which in turn affects ecosystem carbon cycling. All of this means that whilst rainfall is a limiting resource in drylands, nonrainfall sources of water may also be vital to some taxa.

Dryland Shrubs as “Ecosystem Engineers”

Owing to the limited availability of soil moisture, dryland plants typically form only a partial cover on the soil surface, and are characteristically arranged in patches, clumps, or groves (Fig. 6). Individually, and in these clusters, the plants produce changes in the soil (such as the concentration of stemflow water and materials dissolved in it), but also nutrients gathered by spreading root systems, that help to support the plants. Often, shrubs grow on small mounds of fine sand and silt, partly built of particles trapped from wind transport, and partly from particles splashed from the surrounding unvegetated soil by the beating action of rain. Once beneath the

Fig. 6 Plants in drylands are often scattered, forming an incomplete cover. This can be seen in these two images of scattered shrubs (*Cassia* spp.) growing on stony dryland soils (*upper* photo) and a plain carrying primarily scattered chenopod shrubs (*lower* photo). In the lower photo, some scattered tall shrubs (*Acacia* spp.) can be seen on the low ridge in the background.

shelter of a plant canopy, soil particles are less likely to be splashed out again, and so tend to accumulate. Clusters of plants also provide mutually beneficial effects such as sheltering from wind and shading from sun. However, these beneficial or “facilitative” effects are offset by competition among the plants for nutrients and especially for soil moisture. Because of the diverse effects of plants on the soil in their immediate vicinity, they are considered to be “ecosystem engineers”; often the outcome is the formation of favorable micro-habitats that can assist other plants to become established, as well as an enhanced ability to survive dry conditions (Segoli et al., 2008). The areas modified by plants have been referred to as “fertile islands” (Schlesinger et al., 1996).

The patchiness of dryland vegetation extends in spatial scale from individual plants surrounded by unvegetated soils, to clusters of plants a few m in size, to groves that may have dimensions of hundreds of meters. Where plants are clustered and facilitative and competitive effects arise, geometrically regular patterns may emerge, among the most striking of which are the contour-aligned groves known as “tiger bush” (Fig. 7). These patterns are hypothesized to be “emergent patterns” that arise from the plant interactions and the ways in which they alter the availability of soil moisture, especially the positive feedback in which the soils close to plants show higher infiltrability. This constitutes a positive feedback effect, in which groves become favorable habitats, and bare soil becomes a hostile habitat. The beating action of rain on bare soils can produce thin seals or crusts that limit the infiltrability of the soils, and encourage overland flow directed toward plants downslope. Large bare areas can support large groves of plants downslope; areas downslope of plant groves are likely to receive little overland flow, and hence tend to become bare. As these interactions occur through repeated cycles of rain, plant growth, and drought stress, the locations of plants becomes organized in a way that is ecohydrologically efficient, with bare areas adjoining groves of plants immediately downslope. The resulting emergent vegetation patterns such as tiger bush thus provide a form of adaptation to water scarcity that involves the action of many individual plants; they are community-level adaptations, rather than the individual adaptations seen in plants with specially-adapted leaves, root systems, or drought tolerance.

Let us consider the ecohydrologic operation of patterned vegetation a little further. Components of the vegetation mosaic that are unvegetated have low infiltrability, and are source areas for shallow Hortonian overland flow. This moves downslope to locations where the higher infiltrability of groves allows the water to be infiltrated to support plant growth. In this way, the groves of

Fig. 7 Community-level adaptations to water scarcity include these striking, contour-aligned grove and inter grove ecosystems, known as “tiger bush” because of the stripy appearance. The tiger bush landscapes shown are developed in Mitchell grass (*Astrabla* spp.) growing in the Broken Hill district of western New South Wales, Australia (upper photo) and in mulga (*Acacia* spp.) growing in the Alice Springs district of central Australia (lower photo).

plants receive both direct rainfall and the additional runoff water from upslope. The groves offer higher infiltrability owing to several effects of the plants and associated organisms (ants, termites): more biopores, better soil structure owing to the addition of organic matter, less raindrop impact crust development owing to shelter by the plant canopies and litter. Surface runoff is also slowed by the plants and litter and the greater surface roughness that results, allowing more opportunity time for infiltration. In this way, unvegetated and impervious intergroves may take in perhaps 50% of the incident rainfall, whilst groves take in 200%, depending on the relative widths of the intergroves and groves (the relative widths are known to vary with the dryness of the climate). Because of the concentration of water within the groves, the total biomass of vegetation that can be supported is increased by the tiger bush structure over what would be possible with a low but uniform vegetation cover of scattered, isolated plants.

Biological Soil Crusts and the Fate of Rainfall

Microphytic plants are able to colonize the uppermost millimeters of the soil surface in drylands, where their metabolism is supported by falls of rain too small to benefit vascular plants, as well as water extracted from fog and dew fall. Their presence confers erosional stability to the soils, but also affects the partitioning and disposition of rain arriving at the ground, including infiltration and water retention. [Lange et al. \(1994\)](#) investigated the water relations of lichen crusts in the Namib desert, where the annual rainfall is a mere 13 mm or so, falling on just 1–5 days per year. They showed that nocturnal respiration could begin as a result of moisture derived from fog or dew, and that water uptake by the biological soil crusts after heavy fog was 0.49–0.73 mm rain equivalent. These biological soil crust organisms are classified as “poikilohydrous,” having the capacity to exist in a dormant state once desiccated, but able to resume respiration once re-hydrated. Summed across all the rainfall events in a year, moss crusts in the Negev desert can intercept in total up to 5–7 mm of rain, but this does not significantly reduce soil wetting in larger rainfall events ([Kidron, 2014](#)). Other biological crusts are considered to enhance infiltration ([Eldridge and Greene, 1994](#)). There are undoubtedly variations in the ecohydrological role of the diverse forms of biocrusts in different environments. For a review, the reader is directed to [Weber et al. \(2016\)](#).

Dryland Responses to Climatic and Environmental Changes: Vulnerability and Resilience

Expansion of Arid and Semi-Arid Regions Globally

As we have seen, globally, the drylands cover 30% to > 40% of the ice-free land area (the range reflects the various ways in which dryland boundaries can be defined). However, climate change and variability, perhaps related to rising concentrations of CO₂ and other greenhouse gases in the atmosphere, together with feedback processes, involve an increase in global mean temperature. Global mean temperatures do not reveal significant regional differences in the pattern of climate warming, and the drylands are a notable instance of this. In fact, the drylands have exhibited the largest warming, accounting for more than half the continental warming ([Huang et al., 2017](#)). The warming in turn is associated with increasing ET losses from the landsurface in many but not all drylands, and hence in increasing values of the index of aridity (P/PET; P = precipitation, PET = potential evapotranspiration).

[Huang et al. \(2016\)](#) reported accelerating expansion of the global drylands. Using corrections to the Fifth Coupled Model Intercomparison Project (CMIP5), they showed that it was probable that drylands will expand to cover more than half of the global land area by the end of the 21st century. Exact figures depend upon which Representative Concentration Pathway (RCP) is used to project future CO₂ levels. Under RCP8.5, global dryland area would increase by 23%, but by a smaller 11% under the RCP4.5 scenario of reduced emissions, relative to the 1961–90 baseline area. Huang et al. speculate that the dryland expansion will reduce carbon sequestration there and so will contribute to further regional climate warming, posing risks to the sustainability of the affected drylands. Expansion of the semi-arid drylands, which cover the largest area of dryland globally (~ 15% of the land area), has been reported to have increased by 7% between the 1948–62 data and the 1990–2004 data ([Huang et al., 2016](#)).

Drought and Ecohydrology in the Global Drylands under Climate Change

Scenarios of the future warmer global climate forecast widespread increases in the risk of climatological drought ([Carrão et al., 2018](#)), though the change in risk is not uniform across the globe. However, knowledge of likely changes to P and PET are insufficient to estimate how the dryland ecosystems will respond. The response of plants to the additional atmospheric CO₂, which will make carbon more readily available, will be to need fewer stomata across which gas exchange can occur. If plants reduce stomatal numbers and/or stomatal conductance, this will have the associated effect of reducing plant water loss. Ordinarily, plants close their stomata in response to triggers in atmospheric humidity and temperature, in a way that protects the plant from desiccation. Reduced stomatal opening related to the additional atmospheric CO₂ is envisaged to compensate for much of the apparent increased aridity suggested by P/PET indexes, since PET does not correspond to actual ET when plants limit their transpiration ([Swann et al., 2016](#)). Uncertainty remains about the extent to which these ideas are generally applicable across the global drylands. Almost certainly, local ecosystem structure and floristics, especially the ability of different taxa to access limited soil water reserves during drought, depending on characteristics such as rooting depth, will result in considerable regional variation in the outcomes for dryland environments and organisms.

Drylands contain ecosystems that are frequently under stress, from nutrient scarcity, moisture shortage, or high temperatures and desiccation. Niches within the drylands, such as along the corridors of ephemeral dryland streams and rivers, or in the sheltered

micro-environment beneath stones, support distinctive local communities of organisms, from microbes to large trees. In this situation, a change in stress or resource availability can be expected to result in shifts in ecosystem composition or functioning. It is worth considering what changes have been seen in the global drylands during the historic era, and what changes might be expected in coming decades, in a warmer world with an invigorated hydrologic cycle.

Encroachment of Woody Plants in the Drylands

Over the last century or two, grasslands in many regions have been progressively experiencing increased occurrence of woody plants such as shrubs and trees. The ecological and environmental controls on the distribution of trees and grasses within savanna and other semi-arid landscapes are complex and still debated. However, fire is likely to be one of the key determinants of tree cover. It has been hypothesized that the rising levels of atmospheric CO₂ may be benefitting trees, contributing to the observed increase in woody plants. Grasses have a C3 metabolic pathway, whilst woody plants have the C4 pathway (Franks et al., 2014). There are several other hypotheses, including the reduced stomatal conductance mentioned above. This could allow the woody plants to access an additional water resource made available by reduced transpiration by grasses. Grazing effects may also be involved, with less palatable taxa expanding at the expense of preferred fodder species.

A trend to global greening has been observed in satellite data, and has been associated with a rise in global land evapotranspiration. The greening trend occurs even in the drylands. Changes in plant architecture are also occurring as growth conditions alter, affecting the leaf area index (LAI) and other properties. All of this is significant because the nature of the vegetation affects the global climate and hydrological cycle. For instance, it has been argued that reduced stomatal opening and associated reduced transpiration have had a detectable impact on global river flows, which may have increased through the 20th century in response.

Ecohydrological processes involve far more than transpiration, however. When woody plants encroach on formerly grassy drylands, other processes can be affected. These include the canopy interception of rainfall, the infiltrability of soils, the delivery of water as stemflow to locations close to the stems of plants, and, overall, possible changes in the pattern of soil moisture and of recharge to groundwater. These changes may then contribute to further changes in the vegetation, via feedback loops. Ecohydrology, especially during a period of climatic change, presents many complex challenges to understanding, and monitoring of ecosystem responses to environmental change will be required in coming decades in order to test the various hypotheses just outlined.

Collapse of Self-Organized Dryland Vegetation Systems

As noted earlier, many drylands contain mosaic vegetation patterns, exemplified by tiger bush. The origin and controls on these emergent patterns remain topics of research and debate. However, a number of authors have hypothesized that climate change, especially increasing aridity or drought occurrence, poses a risk to these landscapes. Mosaics are seen as an intermediate state between full vegetation cover and a completely bare surface, and vulnerable to moving toward a complete lack of vegetation in the face of more limited available soil moisture in a future warmer world. However, once again this is a complex issue that depends on local or regional climates of the future, as well as on the response of particular local plant taxa to those altered conditions. Presently, there is insufficient knowledge of many of these issues to be completely confident about the fate of emergent vegetation patterning in the drylands. It has been shown that isolated plants, lacking the facilitative effects of close neighboring plants, can nevertheless achieve higher water use efficiency; mechanisms such as this may confer resilience on patterned vegetation during any tendency to decline in plant cover.

Precipitation in a Future Warmer World

The climatic environment of drylands involves high rainfall intensities. An important issue is how these intensities might change in coming decades. As noted earlier, fog and dew can be critical moisture sources in drylands, and therefore it is also important to consider how the availability of these may change.

A warmer atmosphere can hold more water vapor, and according to the Clausius-Clapeyron relation, the capacity increases at 7% °C⁻¹. Given that this may result in more precipitable water in the atmosphere, it is likely that the intensity of rainfalls will increase in the future. In terms of ecosystem rainfall partitioning, this suggests that an increasing fraction of the rain in extreme events may be partitioned into overland flow, rather than into locally plant-available soil moisture. On the other hand, the occurrence of dew and fog may increase if the atmospheric water content rises. There have been many investigations of temporal trends in rainfall intensities, though primarily examining only statistics of daily or hourly values, rather than sub-hourly intensities. Some have found evidence of an historical decline in intensity, and some have detected increasing trends. In many cases, the pattern of change is geographically complex, with different areas exhibiting different trends or rates of change. As we saw earlier, subhourly rainfall characteristics are important in ecohydrology, perhaps more than they are in general climatology. This is because infiltration and water partitioning at the soil surface, interception in plant canopies, and the delivery of stemflow, are all known to be strongly influenced by rainfall intensity. Short-term rainfall intensities are often assessed over periods of 10–30 min, and related to the kinds of ecohydrologic processes just mentioned. Such studies require rainfall data having high temporal resolution.

The remaining uncertainty about many of the ecohydrological process, and of possible changes in them in a warmer world, provides a strong motivation for continuing our efforts to understand dryland ecohydrology, and for ongoing monitoring of the responses exhibited by dryland ecosystems to the changing hydroclimate of the coming decades.

Conclusions: Revisiting the Ecohydrologic Definition of “Desert”

Much of what was discussed above makes it clear that defining “deserts” in terms of ecohydrologic characteristics is not straightforward. Some desert locations show relatively high rainfall intensities, but not all do. However, even if particular desert locations have rain that is no more intense than other locations, the small annual rainfall of deserts means that the duration of rain must be less than elsewhere. If the duration of rain is less, then the duration of nonraining dry time must be larger, and as shown above, this can extend to months in some drylands. Consequently, we might expect to see plant characteristics that permit efficient harnessing of the limited water delivered in widely-spaced falls of rain. These characteristics might include low canopy interception losses and efficient stemflow funneling. In terms of dryland community structure, patchy growth of plants, and perhaps vegetation mosaics with runoff-runon systems, are beneficial characteristics that result in efficient harnessing of available water, and which would not be expected in humid environments where water is generally not a limiting resource. We can also recall the reliance on dew and fog that is seen in some deserts, and especially as a source of moisture for nonvascular plants. Again, whilst fog drip contributes significant amounts of water even in humid forested environments, its ecohydrological importance is greater in the drylands. Therefore, we can conclude that in many ways, our understanding of dryland and their distinctive ecohydrology is advanced by considering the nature and controls of ecohydrological processes such as interception, stemflow, and infiltration. It is clear that a knowledge of annual rainfall and its potential future variability, whilst informative at one level, is insufficient to predict the future of dryland ecosystems. These will certainly be affected by fire, drought, human landuse, and the abundance of CO₂ in the atmosphere, as well as by changes in temperature and in many aspects of rainfall. Consequently, process-based ecosystem and landscape models—supplemented by direct field observation in the drylands, with acquisition of parameterization and validation data—will be required in order to track and understand the changes in the extent and characteristics of the global drylands that may take place in coming decades.

Abstract

Desert oases function as centers and sources of dynamic cultural diversity. Despite their often small size, oases and other springs often contain tightly packed, highly interactive assemblages of upland and wetland obligate plants and animals. Springs function as keystone ecosystems, ecologically interactive points, and refugia within larger geographic areas and across long timescales. Desert oases provide crucial habitat for wild and domesticated biodiversity, and sources of economic well-being and inspiration for humans. In this article, we focus on the springs and oases of the Sonoran Desert in southwestern North America. With a long prehistory of human use and great intensification of exploitation for agriculture, recreation, and urbanization during historic times, Sonoran Desert oases and other springs throughout the world have become highly threatened. Oases have long held archetypal appeal as lush refugia for humans traveling through arid regions. However, these spatially limited, bioculturally rich island-like desert refugia are compelling to the human psyche, and have been mythologized in modern society. The “myth of the oasis” does not scale effectively to large urban settings, and this has set the stage for unrealistic expectations and demands on limited environmental resources in these harsh, arid regions. Nonetheless, this myth has inextricably permeated arid land urban society, creating overdrafts in water use and abstraction that portend ever more serious conflicts of an unsustainable future.

Introduction

Oases in arid lands are desert springs ecosystems that function as centers and sources of dynamic cultural diversity. The term comes from the Demotic Egyptian words *ouahe* or *wahe*, meaning “dwelling place.” As with all springs, oases are places where groundwater reaches the Earth’s surface, often creating lush wetland habitat that are occupied by many life forms, and which can function as ecologically highly interactive focal points in the surrounding landscapes. Aridland groundwater-dependent ecosystems (GDEs) often have orders of magnitude higher biological productivity and biodiversity compared to adjacent uplands. While this is the case for many springs types, oases are focal points for human evolution, culture, engagement, and association with arid landscapes (Kreamer et al., 2015; Stevens and Meretsky, 2008). The term oasis evokes an image of cultural context in which humans balance use and sustainability of scarce resources, creating a fine-scale, local refugial niche amidst inhospitable surroundings (Laureano, 2001). However, over the course of human cultural development and history, the concept, dream, and reality of the oasis have been extended to include desert cities, such as those in the Middle East and the American Southwest. Scaling up and extending the oasis concept to large urban settings sets the stage for unsustainable expectations and demands on limited environmental resources.

In this article, we focus on the biodiversity and consequences of human socioecology on oases in the Sonoran Desert in southwestern North America (Fig. 1). The Sonoran Desert covers roughly 260,000 km² in the southwestern United States and northern Sonora in Mexico. Springs distribution data in Mexico are not known to us, but nearly 1000 springs have been reported in the Sonoran Desert in Arizona and California, and if springs density is relatively consistent across the entire Sonoran Desert, we estimate that more than 2000 springs exist in the Sonoran Desert, a density of slightly less than 0.01 springs/km². These springs often are the only water sources in large areas, and vary tremendously in terms of their size, water quality, species diversity, ecological significance, structure, cultural history, contemporary use, and conservation status. Given the isolation and biocultural richness and importance of its springs, the Sonoran Desert is an ideal region in which to examine how regional ecohydrology influences oasis ecosystem form, function, conservation status, and roles in aridland societal development.

Jenness (Museum of Northern Arizona Springs Stewardship Institute, Flagstaff), with base cover derived from <http://maps.tnc.org/files/shp/terr-ecoregions-TNC.zip>, and springs distribution data from MNA-SSI.

Characterization of Sonoran Desert Springs and Oases

Springs emerge in terrestrial and aquatic (including marine) environments. Springs can be perennial, seasonally ephemeral, or have periodic or erratic emergence intraannually and among years. Springs flow can be immeasurably small, or sufficiently large to create large wetlands, rivers, and even lakes. The largest reported springs ecosystem on Earth is reportedly Dumanli Spring in Turkey (mean flow = 5.03×10^4 L/s; [Karanjac and Günay, 1980](#)). Springs water can be cold, warm, or geothermally hot, and have low to very high concentrations of solutes, depending on the hydrogeology, flow path, and aquifer lithology.

Classification and definition of a clear lexicon are required for any field of scientific inquiry, and establishing those prerequisites is long overdue for the field of springs ecosystem ecology. Despite their often small size, springs ecosystems are enormously complex, each with particular groundwater flow paths that vary from a few hours for those near recharge areas, to millennia and long distances for aquifers with low hydraulic conductivity. Groundwater emergence onto the Earth's surface is usually driven by gravity, but also can be pushed by geologic processes or gas. Flow path and aquifer conditions can determine springs geochemistry, temperature, flow rates, and consistency, all of which may be extremely constant or highly variable and diverse.

Springs emergences generate aquatic, wetland, and riparian habitats that function in remarkably individualistic fashion, and even closely adjacent springs are rarely similar in all ecological details. Springs ecosystems often develop in complex landscapes, and usually are small, making them difficult or impossible to detect on aerial photographs or through remote sensing. However, some springs are so expansive they create hundreds of hectares of aquatic and wetland habitat. Springs and sometimes lakes create the headwater base flow of all streams and rivers in nonice-dominated landscapes on Earth.

In the Sonoran Desert, precipitation (including snowmelt) infiltrates aquifers through recharge zones, often at the base of mountains (mountain front recharge). Aquifers are formed by alluvial fill of unconsolidated sand and gravel in basins, permeable sedimentary rocks such as sandstones and limestones, and heavily fractured volcanic and crystalline rocks. Springs often form at the contact between an aquifer and an aquitard such as impermeable shales, mudstones, claystones, siltstones and dense crystalline rocks. Groundwater percolating through the higher permeability strata reaches the aquiclude or aquitard and flows along it horizontally, or nearly so until it emerges in a geologic fracture or fault on a canyon wall, a hillslope, or an escarpment edge. The high geologic and geomorphologic complexity of the Sonoran Desert allows for the emergence of thousands of springs, particularly from small aquifers on mountain flanks. The largest Sonoran Desert springs may be Blue Springs, a complex that emerges in the lower Little Colorado River, with an average flow of about 6.37×10^3 L/s. This perennial flow supports the highest abundance and diversity of native desert fish in the Southwest.

Variability in springs characteristics has proven to be a daunting challenge to hydrologists, who have argued without resolution for more than a century over potential ways to classify springs. Springs' enormous geomorphological and ecological diversity generates ecosystem complexity that transcends traditional discipline-based classification and requires collaborative engagement among

the fields of hydrology, ecology, and anthropology. Such collaboration is both difficult and rare, but without it, the recognition of springs and oases as focal sociocultural ecohydrological habitats has not occurred. This lack of consensus on springs classification has directly led to the ubiquitous, but largely ignored degradation and loss of these important ecosystems.

To address the challenge of springs classification, [Springer and Stevens \(2009\)](#) developed a comprehensive terrestrial springs classification system, describing 12 springs types, all but one of which occur in the Sonoran Desert ([Table 1](#); [Figs. 2-3](#)). Among these, many hillslope, helocrene, limnocrene, mound-form, gushets, and hanging gardens springs types have been extensively modified by humans, and qualify as oases. Hillslope springs, which allow the use of gravity to transport water across human-dominated landscapes are common water sources for desert oasis agricultural irrigation.

Adding greatly to the ecological complexity of springs is the cooccurrence within springs of as many as a dozen different geomorphic microhabitats, each of which is generated by discrete physical processes, and each supporting its own suite of species. These microhabitats can include bedrock surfaces, pools, channels, terraces, spray zones, and hyporheic zones below the channel floor, among others ([Springer and Stevens, 2009](#)).

Evolutionary Ecology and Diversity

Oases and other springs are complex ecosystems with diverse ecological and evolutionary processes and functions. In arid regions, such as the Sonoran Desert, springs often are differentially highly productive ecosystems located in areas of relatively low productivity. Despite their often small size, they contain tightly packed, highly interactive assemblages of both upland and wetland obligate plants and animals. Thus, springs function both as refugia and as keystone ecosystems—ecologically interactive points within larger geographic areas. Depending on their age, geomorphology, isolation, and specific environmental and biogeographic histories, some springs function as paelorefugia, supporting high levels of endemism because they provide environmental constancy through evolutionary time. Many species, including humans have survived episodes of glaciation and global warming, desertification, and shifting precipitation at, or by seeking out springs refugia ([Nekola, 1999](#); [Cuthbert and Ashley, 2014](#)).

Springs-dependent species are those that rely on springs habitat for at least one phase of their life histories. The processes of relictualization and adaptation have led to the evolution of a wide array of springs-endemic species that are closely adapted to thermal or physiochemical conditions at specific springs. Prominent among these springs-dependent taxa in the Sonoran Desert are aquatic springsnails (Hydrobiidae, especially the hyper-diverse genus *Pyrgulopsis*), dryopoid beetles (Dryopidae and Elmidae), pupfish (Cyprinodontidae), and many poorly-known or unstudied invertebrate taxa. Low-elevation, endemic springs plant species primarily include alkaline soil specialists, while potentially endemic springs riparian invertebrates have not received much scientific attention. Through relictualization, springs-dependent populations become even more restricted in distribution under harshening, adverse environmental conditions, but through adaptation those populations also may expand when environmental harshness relaxes.

One of the older springs complexes in the Sonoran Desert appears to be Montezuma Well in the Verde River in central Arizona ([Blinn, 2008](#)). This collapsed carbonate mound springs ecosystem forms a 120 m-wide pool that is 16 m deep, and lies in a kilometer-wide travertine paleosprings complex ([Fig. 4](#)). Its unithermal, carbonate- and arsenic-rich waters create a highly productive, fishless ecosystem that, due to the processes mentioned above, support at least five endemic springs-dependent invertebrate species and an endemic diatom, the highest concentration of unique species at a single point in North America, to our knowledge ([Fig. 5](#)).

Table 1 Springs classification system ([Springer and Stevens, 2009](#)).

<i>Spring type</i>	<i>Description</i>
Cave	Groundwater emerges in a cave system, typically in karstic aquifers with large conduits.
Exposure	Exposure of groundwater at the Earth's surface in a fracture or sinkhole.
Fountain	Focused groundwater flow forced out of the Earth by head pressure from a confined aquifer.
Geyser	Explosive flow of hot water from a confined aquifer (the only springs type not found in the Sonoran Desert).
Gushet	Discrete springs flow gushes from an escarpment or steep slope of perched, unconfined aquifers, often along fracture zones.
Hanging Garden	Water emerges from indistinct or multiple sources seeping from shallow, unconfined aquifers. These often form in canyons of layered sedimentary rocks, where underlying formations have been weathered back from a harder, impermeable layer above.
Helocrene	Groundwater emerges diffusely in a marshy, wet meadow or low gradient wetlands, often with indistinct or multiple sources seeping from shallow, unconfined aquifers.
Hillslope	Springs form from unconfined aquifers on a hillslope, often with indistinct or multiple sources of flow.
Hypocrene	Shallow buried springs where flow does not reach the surface, but is expressed through wetland vegetation. This is also a transitional state of springs that are being dewatered, either naturally or through anthropogenic groundwater withdrawal.
Limnocrene	Groundwater emerges in a pool, often with relatively uniform temperature and chemistry.
Mound Form	Groundwater creates a organic, mineralized (often carbonate or travertine) or ice (e.g., permafrost-zone pingos) mound.
Rheocrene	Flow from springs emerges into a stream channel.

The composition of species assemblages at springs is shaped by topography, isolation from other similar springs, the size of the wetted area, environmental stochasticity, and the sequence, life history strategies, and genetic constitution of colonizing species. Old and environmentally constant springs ecosystems can function as paleorefugia, supporting a few to many endemic species, whereas highly variable or newly formed springs function as neorefugia, supporting widespread weedy species with long-distance dispersal mechanisms, including nonnative taxa. Nonintuitively, nonnative plant species richness is positively related to that of native species at springs. This is likely due to the elevated productivity of springs that, when disturbed by natural or anthropogenic mechanisms,

are quickly colonized by weedy species. Springs function as stepping stone refugia, serving as stop-over points for migrating or dispersing birds and mammals, as well as supporting unique combinations and assemblages of microbes, plants, and animals. Springs may support metapopulations, interconnecting sink and source populations that, with periodic connectivity, can maintain species over long time periods. Springs also are settings in which frequent connectivity through animal migration or human trade introduce complex suites of species that can survive and persist in the favorable oasis environment. These processes highlight the tension between isolation and episodic connectivity that characterize immigration, colonization, and extinction in springs ecosystems. The dueling ecological impacts of isolation and environmental connectivity can create highly stable and resilient springs habitats over time, but can render others fragile and highly susceptible to human-induced degradation (Fig. 6).

Indigenous Use of Springs Ecosystems

Springs have played an integral role in human ecology and evolution in arid zones throughout the world. Our hominin ancestors repeatedly retreated to springs in the Olduvai Gorge during dry phases (Cuthbert and Ashley, 2014). In the Sonoran Desert, springs ecosystems served as vital locations for prehistoric peoples and societies, and as such, have a long history of human management. Archeological investigations at relic springs sites in the Sonoran Desert reveal fossil and carbon evidence that early Clovis cultures used springs to ambush Pleistocene megafauna, such as mammoths, camels, and bison at the end of the last ice age 13,000 years ago (Haynes Jr, 2008). Springs at that time served as nuclei for hunter-gather cultures because of their concentrated water, plant, and animal food resources. Subsequently, and with the invention of agriculture, springs played an integral role in human settlement, cosmology, and transition to farming in the Sonoran Desert.

The complex topography of the Sonoran Desert gave rise to oasis cultures different than those of other drier, more formidable deserts. In the Sonoran Desert, annual rainfall varies from 3 to 20 in. with a distinct, bimodal precipitation regime of intense summer monsoons, and low-intensity winter storms. Elevations range from below sea level at points on the Baja California peninsula to over 3,050 m (10,000 ft) in the Sky Islands of the Sierra Madre and ranges of southeastern Arizona. Oases of the Sonoran Desert and Baja California peninsula are rugged and resemble the Old World desert oases of the Arabian Peninsula and North Africa, with lush green vegetation sharply contrasting the surrounding hyper-arid desert (Fig. 7). Sonoran Desert springs exhibit diverse habitats, including seeps, plunge pools, ciénegas, and narrow canyon streams, as well as ephemeral runoff-supported wetland and riparian ecosystems. Indigenous exploitation of these environments was as spatially and temporally diverse as the landscapes of their inhabitation.

Early prehistoric cultures of the Sonoran Desert practiced a type of proto-agriculture, encouraging, and later collecting seeds and actively irrigating plant species native to the region (Mabry, 2005). In southeastern Arizona, these species included goosefoot (*Chenopodium* spp.), amaranth (*Amaranthus* spp.), tansy mustard (*Descurainia* spp.), Indian rice grass (*Oryzopsis hymenoides*), dropseed grass (*Sporobolus* spp.), native tobacco (*Nicotiana* spp.), and possibly native cotton (*Gossypium* spp.) Archeological research dates

the use of these proto-crop complexes to 5,000–3,000 years before present (y.b.p.). Mesoamerican crop species arrived to the Sonoran Desert 4,500–2,500 y.b.p., either through migration or diffusion, including maize (popcorn) (*Zea mays*), pepo squash (*Cucurbita pepo*), common bean (*Phaseolus vulgaris*), bottle gourd (*Lagenaria siceraria*), and possibly domesticated cotton (*Gossypium hirsutum*). From 1,500 to 900 y.b.p. tropical cultivar complexes arrived in the region, including flour corn (*Zea mays*), jack bean (*Canavalia ensiformis*), cushaw squash (*Cucurbita mixta*), butternut squash (*Cucurbita moschata*), and domesticated tobacco (*Nicotiana rustica*). During that phase, archeological and historic records indicate that additional native Sonoran Desert plants were domesticated, including tepary bean (*Phaseolus acutifolius* var. *latifolius*), agave (*Agave* spp.), little barley (*Hordeum pusillum*), panic grass (*Panicum sonorum*), and devil's claw (*Proboscidea parviflora* var. *parviflora*).

The Santa Cruz River in Tucson, Arizona was a perennial stream, with a lush riparian environment created by a perched aquifer. Indigenous cultures managed the intermittent flow of this riparian system basin for almost four millennia. Excavations at the site of Las Capas, northwest of Tucson near the confluence of the Santa Cruz and Rillito Rivers, revealed 3,200-year old irrigation canals, with diversion channels and gridded gardens (Mabry, 2008). The later Hohokam culture (450 CE) reconstructed these irrigation systems, and also developed additional farming and water-management technologies to survive in the arid, highly variable climate of the Sonoran Desert. The Hohokam practiced floodwater farming on lower mountain slopes and arroyos, capturing and spreading ephemeral flows laden with nutrient-rich organic debris onto agricultural fields. They also directed overland sheet flow with simple rock berms to intercept and concentrate stormwater. They built small mounds of rocks to hold extra moisture for dispersed agave cultivation across hundreds of hectares of the lower mountain bajadas (Fish and Fish, 1992).

Likely descendants of the Hohokam, related O'odham tribes later inhabited the Sonoran Desert. The Tohono O'odham lived in the mountain foothills during the winter, and moved to farming camps or villages along desert washes in the summer. They employed a technique called *ak-chin*, or flood irrigation farming, diverting springs and ephemeral floodwaters during summer monsoon storms from small washes to floodplain fields. They planted cottonwood and willow trees in living fencerows to help slow, direct, and spread the nutrient-dense floodwaters over their fields. When the waters receded, they planted many different traditional crops, such as varieties of corn, beans and squash in the fertile, moist ground. These low-tech landscape strategies included shallow contour terracing created by placing lines of single stones, diversion walls, grids, and living fencerows—all methods of capturing limited water resources and creating a positive environmental niche in an arid environment to allow cultures to thrive for millennia in the harsh environment (Nabhan, 1983).

Rea (2008) describes how springs in the Sonoran Desert and US Southwest often are sites of legends, creation sagas, mythical creatures, and divine beings. In some creation beliefs, springs were not only sources of sustenance, but sources of life, where clans emerged from other dimensions to live on the Earth. Such springs were and remain keystone cultural foci, providing not only basic living resources, but a landscape connection to history and a sense of cultural reconnection and meaning for future generations. The famous water serpent emerges in many tribal cosmologies as the sacred guardian of springs. A persistent belief in Sonoran cultures today, the divine beings that occupy/create springs must be honored and respected to maintain the perpetuity of water and societal well-being. If the serpent is killed, the water and human culture will disappear.

Old World and New World Influences in Oasis Agriculture

Jesuit missionaries first arrived to the Sonoran Desert from central Mexico in the late 1600s, bringing with them a complex suite of Old World beliefs, agricultural practices, and species (Sheridan, 2004). In colonial fashion, these were injected into indigenous Mesoamerican land use practices and native plant assemblages to create novel socioecological systems. Jesuits and other Spanish colonizers implemented their own, larger canal irrigation systems, called *acequias*, from the Arabic *as-saqiyya*. The missionaries forced indigenous neophytes to dig an *acequia madre*, or “mother” ditch to intercept springs outflow. That canal delivered water to lateral ditches to irrigate fields and orchards. They lined some of the canals with rock or lime mortar, and in places created holding ponds to regulate the flow of water to the fields. Jesuit missionaries implemented these irrigation and farming systems as an integral part of their evangelizing colonization strategy. By controlling water supplies, the missions quickly became centers of *reducción*, concentrating and converting indigenous tribes to Catholic life and beliefs.

The Jesuits introduced a largely Mediterranean oasis crop repertoire that included species available in Europe, the Middle East, North Africa, and the Canary Islands, and several newly acquired species from the New World. They introduced perennial species, such as figs, grapes, olives, citrus, quince, peach, apricot, apple, pear, pomegranates, dates, and bananas, and annual crops such as wheat, corn, barley, beans, garbanzos, rice, cotton, watermelons, melons, squash, onions, beets, garlic, yams, tomatoes, lettuce, radishes, and peppers. They also brought domesticated livestock, including horses, burros, sheep, goats, and cattle. Using these strategies, the Jesuits established a succession of missions along river valleys, advancing northward through the Sonoran Desert.

On the hyper-arid and rugged Baja California peninsula, the shock of Jesuit missionary arrival and cultural transformation was more severe. The extreme topography of the central peninsula precluded subsistence agriculture, limiting indigenous lifeways there to nomadic, hunter-gathering practices. During their 70-year ecclesiastical reign on the peninsula (1697–1768), Jesuits enforced the *reducción* of the nomadic Pericú, Guaycura, and Cochimí peoples into sedentary, agrarian lives (Crosby, 1994). Cultural conversion was concentrated on isolated spring-fed oases, where they developed terraced fields and *acequia*-style irrigation systems. As elsewhere, the Jesuits introduced Old World crop and livestock species, as well as New World species from the North and South American mainlands. Those oases were changed into complex agroecological systems with livestock, stratified cropping, terraced fields, and canal systems. The crop repertoire within each oasis thus reflected cumulative geographies of agricultural and cultural colonization and dissemination.

Studies of Baja California oases reveal that as these ecosystems provide refugia for wild species, they also serve as in-situ crop refugia (de Grenade and Nabhan, 2013). Within 241 oasis *huertas* (field gardens) surveyed in the 2010/2011, a total of 89 species of perennial food crops, belonging to 64 genera and 36 families were recorded (Figs. 8–9). These included 21 perennial species introduced by Jesuit missionaries, as well as newer arrivals. Oasis *huertas*, which hold both native and introduced species of flora and fauna, are still managed as diverse agroecosystems. They are, in most cases, small-scale farming systems that integrate crop rotation, livestock, mixed annuals and perennials, and crop tiering. In many gardens, perennial fruit plants grow along the irrigation ditches and form hedgerows between fields, providing shade, windbreaks, and attraction for insectivores and pollinators. Fields are planted with forage crops, grains, legumes, and vegetable crops, or rows of perennial fruit crops, nopal (*Opuntia* spp.), or vine crops. Livestock, including cattle, burros, sheep and goats are grazed in the gardens

during fallow periods, or tethered to tall trees and palms and fed grass and herbaceous plants harvested by sickle. This fine-scale, mixed-method agriculture offers a defense against pest epidemics, drought, and floods and enables long-term viability of farms and farm families.

These biocultural oases exhibit species-packing and structural diversity; as [Rosenzweig \(1995\)](#) noted in wild systems, the more species that coexist in a particular space, the more niches they distinguish within that space. In oasis gardens, the more complex the garden structure, the more agriculture species are likely to be found. Agricultural space also is managed in temporally diverse methods, including multi-story cultivation systems, a careful mix of perennial and annual species, integrated livestock use, and alternate fallowing of terraces. Native fan palms (*Washingtonia* spp.) are the most characteristic keystone species of these oases, hosting numerous insect visitors and pollinators and providing shade, food, and habitat for resident amphibians, reptiles, birds and mammal species, as well as migratory or overwintering species ([Cornett, 2008](#)). Naturalized date palms (*Phoenix dactylifera*) now grow intermixed with native *Washingtonia* palms and have become a novel keystone species in the new guilds of wild, weedy, and domesticated species. In these ecosystems, the greatest agrobiodiversity and biodiversity often are associated with traditional land management approaches, where low-levels of mechanization are employed in cultivation. Small sections of fields are tilled for annual crops, while other sections are used to grow perennial fruit trees, vines, and forage crops. Fields with the lowest biodiversity are those that are abandoned and those that have been converted to industrial agricultural practices.

Biodiversity and agrobiodiversity within spring-fed desert oases distinctly reflect human cultural and political processes through time. Studies of two small oases in the Sonoran Desert, Quitovac, Mexico and Quitobaquito, Arizona, located within 25 miles of each other on each side of the United States-Mexican border, have shown how oasis flora has been differentially determined by Indigenous, colonial, industrial, and political forces. Elevated wild plant and avian diversity was recorded in Quitovac, where traditional Tohono O'odham and Spanish agricultural practices support a greater diversity of wild and domesticated crop species than at Quitobaquito in Arizona, where the supporting springs are now part of Oregon Pipe National Monument and isolated from continued farming and ranching practices ([Nabhan et al., 1982](#)). Surprisingly, this elevated biodiversity at Quitovac has persisted even though the springs and surrounding community have been heavily degraded by bulldozing, draining of the lagoon, groundwater extraction, gold mining, population growth, woodcutting, and grazing. Traditional cultural and farming practices support a mix of wild, weedy, and domesticated species assemblages. Anthropogenic forces, however may prove too intense as modern agriculture and industrial practices expand in the region and traditional practices wane.

Urban Up-Scaling the Myth of the Oasis

Oases throughout history have served as the intersections of cultural development and trans-continental and intercontinental trade routes. As a result of their abundant productivity, biological diversity, and general appeal, springs have become one of the most threatened ecosystems on Earth, particularly in arid regions. In the Sonoran Desert, this process began with overgrazing and intensification of agriculture, mining, and sophistication of groundwater extraction technology. Rapid agricultural expansion led to unsustainable rates of groundwater use that have been magnified as urban and suburban expansion supplants agriculture. Interbasin water transfer from the Colorado River via the Central Arizona Project facilitates ever higher rates of water use for agriculture, industry, and urbanization throughout the "sunbelt" of the Sonoran Desert. The tremendous growth of desert cities such as Phoenix, Tucson, Casa Grande, and the surrounding metropolitan areas have placed significant stress on water resources. The region's vast aquifers and thousands of springs have succumbed to rural and urban appropriation, agricultural uses, resource

extraction (e.g., for mining and livestock grazing), and recreation. Our ecological investigations in several landscapes in the Southwest revealed that often more than 90% of the springs in lowland landscapes have been ecologically impaired or destroyed by human activities, particularly groundwater depletion and pollution, and by under-informed livestock grazing and land management practices.

Oases in the Sonoran Desert were places of survival and divine significance for indigenous cultures. The oasis concept also has deep Judeo-Christian roots, and the Spanish and subsequent European colonists clearly understood the relationships between water, belief, and social dominion in arid regions. The concept of the oasis applies well to fine-scale agro-management of water sources, but does not scale-up appropriately to inform urban desert landscape development, which is erratically subject to both internal and external forces, with little emphasis on ecological sustainability. Nonetheless, the oasis has been transformed into a myth, the belief that desert lands can be “reclaimed” and transformed into vibrant, green urban spaces. The myth of the oasis has become a central water resource management paradigm behind water use policy and practice in the Southwest. The myth has become deeply embedded into the collective social unconscious, and continues to guide urban development in the Southwest.

Sonoran Desert cities are now heavily dependent on massive interbasin water transfers, and all face diminishing groundwater supplies. As with other desert urban cultures around the world, Sonoran cities generate conflict by bringing together divisive historical and societal beliefs about resource ownership, self-determination, trade, and cultural connectivity, often pitting urban and industrial expansion and values against rural lifeways and agriculture. Such conflicted societal spaces contain deep, inherent conflicts over water scarcity, and at best adopt short-term solutions that ignore potential future deficits and long-term resource management. The urban myth of the oasis clashes with need for each aridland community to recognize that a cornerstone of good governance in the desert is sustainability of water supplies and the ecological integrity of its landscape.

Human activities have greatly reduced the ecological integrity of many wetland, riparian, and springs ecosystems through competing exploitative uses, including groundwater pumping, diversions, fuel wood harvest, recreation, livestock grazing, mining, recreational use, and wildlife management. Many springs have been lost due to the construction of roads and buildings. Others have been depleted by expanding populations of invasive native and nonnative species. Invasive plants and animals often overwhelm native species, disturbing springs ecological integrity. These landscape-level impacts affect the springs source, but also may alter long-term water infiltration, flow, and emergence at distant sites.

At a landscape-scale, springs ecosystems serve as the canary in the coal mine of human-induced global change. As windows into aquifers, springs are some of the most sensitive indicators of climate change. Threats posed by climate change will profoundly affect springs, particularly through declining and faster-melting montane snowpacks, as well as through drought, wildfire, and changing precipitation regimes. These challenges alter ecosystem resilience and dynamics across spatial scale. Fragile but resilient, springs will be subject to heightened anthropogenic pressures; these pressures will elevate extinction risks of the many hundreds of springs-dependent species in the Sonoran Desert and throughout the world.

Assessment and understanding of the extent, duration, and consequences of human impacts on oases and other springs is now emerging (Stevens and Meretsky, 2008; Kreamer et al., 2015). Springs occupy such a miniscule proportion of the southwestern landscape that their demise has gone largely unnoticed. Springs may be part of larger water management systems that are highly altered for urban, mining, and agricultural use that involves complex systems of groundwater extraction and interbasin transfers, masking the fine-scale dynamics of springs and the remaining oases in relation to the landscapes in which they exist. The many external threats to these ecosystems points to the need for improved knowledge of their distribution (the quality of mapping data remains very poor in most landscapes), basic understanding of springs and oasis ecosystem ecology, and refined understanding of sustainable stewardship options.

Sonoran Desert Springs in the Future

Losing oases and springs constitutes a global environmental crisis. However, there are still opportunities for recovery of these ecosystems. If the supporting aquifer is not impaired (many montane aquifers are not), springs ecosystems can be rehabilitated and restored. Springs provide essential keystone ecosystem functions, and conserving small springs can provide cascading benefits on the surrounding landscape. The Museum of Northern Arizona Springs Stewardship Institute (www.springstewardshipinstitute.org) supports sustainable springs management and recovery by providing guidance to those interested in springs inventory, assessment, planning, stewardship, and monitoring. Mapping of springs locations and scientific study of springs ecosystems informs stewards and conservationists, policy makers, and the public. Rangeland health initiatives, rotational grazing and fencing of isolated springs has led to stabilization of some springs ecosystems. In urban spaces, sustainable water management practices such as storm-water detention basins, rainwater harvesting, and arid-adapted urban landscaping can create small oasis-like environments, even in areas where natural groundwater has been depleted. Formal measures, such as the Ramsar Convention list of Wetlands of International Importance, FAO's Globally Important Agricultural Heritage Systems, UNESCO's Man and Biosphere Programme and World Heritage sites, and the Global Geoparks Network have gained traction to help protect the natural and cultural assets of many oases. Intensive efforts at individual springs and water conservation at the landscape scale are critical to maintain the springs ecosystems and biodiversity of desert oases.

Conclusions

Desert oasis ecosystems harbor endemic native species assemblages as well as unique wild, weedy, and domesticated species complexes. Given the small land area that these spring-fed ecosystems occupy, their importance as quality habitat, migratory rest-stops, biodiversity, centers of agrobiodiversity, and economic value in arid regions is vastly underestimated. Desert oases and springs provide critical resources for wild and domesticated biodiversity, but are among the most threatened ecosystems on earth. Enhanced recognition of their importance, better understanding of their ecology and sociocultural significance, and improving stewardship practices are needed to sustain societal well-being and Earth's biodiversity. Oases have long held archetypal appeal as lush refugia for humans traveling through deserts. However, these spatially limited, bioculturally rich island-like refugia are compelling to the human psyche, and have been mythologized in modern society. Unfortunately, the "myth of the oasis" does not scale effectively to large urban settings, and this has set the stage for unrealistic expectations and demands on the limited environmental resources in these harsh, arid regions. Nonetheless, this myth has inextricably permeated aridland urban society, creating overdrafts in water use and abstraction that portend ever more serious conflicts in an unsustainable future. It is time to reconsider the myth of the oasis in relation to planning and management of urbanization in the desert Southwest to better ensure the sustainability of aridlands ecology and society. Is the oasis a suitable paradigm for urbanization of the desert, or is it, along with the dream of a cool July day in Phoenix, a perilous mirage?

Acknowledgments

We wish to express our gratitude to the University of Arizona Southwest Center and the Museum of Northern Arizona Springs Stewardship Institute for support in preparation of this article. The map was created by Jeff Jenness (MNA-SSI GIS Department), and Andrea Hazelton, Alek Mendoza, and Tierney Schipper of MNA-SSI provided welcome comments on earlier drafts.

Abstract

The high levels of rarity and endemism (geographically restricted species) seen in the deserts of the world are largely a result of their geographic distribution, landforms, evolutionary history and biotic interactions. Long histories of isolation and climatic change have resulted in suites of unique species, both young and old, in all major deserts. The biogeographic history of each desert is key to the processes and the evolution of its species, with key examples being latitudinal deserts, rainshadow deserts, sky islands within deserts, and fog deserts. Rainfall pulses and other evolutionary pressures have resulted in surprising levels of convergence between the deserts of the world, with plants and animals taking similar forms, but coming from very different lineages and origins. Excellent stewardship of our global deserts is of key importance to biodiversity conservation worldwide.

Global Distribution Patterns

Most deserts of the world are rich in rare and endemic species, largely due to their evolution in relative geographic isolation. The extraordinary variation in climate, size, age, and evolutionary history of the world's deserts have contributed to their biological uniqueness. To understand endemism and rarity in deserts, we must first look at global patterns of distribution, and then at the evolution and origin of deserts. The fragmented evolutionary history of the deserts of the world has been the driving force of their biological rarity, of adaptation to local conditions, and of specialization to isolated environments.

On a global scale, vegetation patterns (the building blocks of ecosystems) are determined by climate. Plant diversity is highest near the equator in tropical areas ([Kier et al., 2005](#)). [Qian \(1998\)](#) showed that globally, along the latitudinal gradient, generic richness shows a striking increase with decreasing latitude. However, recent research from [Jansson \(2003\)](#) indicates that global patterns in locally endemic taxa are caused by the amplitude of climatic change during peaks of Milankovitch oscillations (every 10–100,000 years). [Stebbins and Major \(1965\)](#) classify endemic species into two main types neoendemics (recently derived endemic taxa) and paleoendemics (relicts from ancient lineages). Neo-endemics may not yet have reached their potential climatic limits if they have not had adequate time to expand their ranges. These two categories of endemism can be difficult to separate without a large amount of inference, but they are significant when considering the modern day patterns of desert endemism. Smaller climatic shifts allow the survival of paleoendemics and diverging gene pools (neoendemics) are able to persist. Using change in mean annual temperature since the last glacial maximum, [Jansson \(2003\)](#) showed that areas which have experienced larger temperature changes have lower endemism in mammals, birds, reptiles, amphibians and vascular plants (robust to area, latitude, extent of former

glaciation and oceanic island syndrome). This research suggests that Rapoport's rule (species range increases with latitude) is a product of the increase in the amplitude of climatic oscillations as you move towards the poles.

The first true desert conditions in most of the world are thought to have originated during the Pliocene, 5–10 million years ago, and expanded gradually during the Pleistocene interglacials. The Namib Desert began to develop in the Early Oligocene as cold water from the Southern Ocean was able to penetrate northwards (Van Zinderen Bakker, 1975). The antiquity of this desert is well reflected in its endemic biota. Climate has changed significantly in the world's deserts since the late Pleistocene glacial period. The Last Glacial Maximum (LGM) was 25–17 thousand years ago, when large ice sheets dominated and the climate was cooler. During this time deserts moved towards the equator, shrinking in the mid-latitudes, where they were replaced by more temperate vegetation types. Many of our modern desert plants and animals took refuge in areas that are now dry subtropical forest. As the glaciers retreated (around 15 thousand years ago) the Holocene period began, which leads us right up to the current Anthropocene climate. Generally, the high-latitudinal edge of the world's desert was colder and wetter during the last glacial maximum but the tropical edge may actually have been drier than it is today. For example, in the late Pleistocene the Chihuahuan Desert of North America harbored woodlands of piñon pines, junipers, and oaks, while the tropical dry woodlands of central Mexico became drier, evolving the extremely rich cactus flora (endemism and diversity) that characterizes this region. Modern warm-desert vegetation in Western North America started becoming extensive < 12,000 years ago (Frenzel, 2005; Raven and Axelrod, 1978; Axelrod, 1978). Holocene climate brought a more intense monsoonal season in sub-tropical regions and deserts moved into the mid-latitudes.

Sky-Islands and Fog Deserts

Much of the endemism within our global deserts is found in isolated outcroppings or sky islands. This is most often the case in rugged and cool mountain ranges that are located within expansive desert plains. The refugial effect allowed the continued existence of species that were extirpated elsewhere. Their isolation for 15–20 thousand years has resulted in many unique genetic traits and new taxa. The biological effects of the LGM were more severe in the northern hemisphere and therefore the sky islands of the north are richest in relictual species. A similar phenomenon is also seen in areas where coastal moisture (fog) creates climatic refugia, allowing the continued existence and proliferation of ancient taxa.

In North America, the relictual "Madro-Tertiary" flora which originated in Mexico, moved north and then was largely extirpated, is well documented in the fossil record (Axelrod, 1950). In Africa, similar relictual ranges are found within the Saharan plains, and the Atlas Mountains in northern Morocco shelter rich pine (*Pinus*) and oak (*Quercus*) forests in a similar fashion. The mountain ranges of south-eastern Algeria and northern Niger harbor a number of endemic and rare Mediterranean species such as tarout (*Cupressus dupreziana*), wild olive (*Olea europaea*), and Saharan myrtle (*Myrtus communis*). The Tibesti Mountains in southern Libya are also home to a relictual flora from the Mediterranean and the tropics. Northern relicts are also present in the Somali Peninsula in the high mountains. In the tip of the Horn of Africa, the Somali Montane Woodlands depend on the marine layer and coastal moisture forming a refuge and center of endemism for plants and animals. The higher part of the ranges is home to species such as kadi (*Murraya koenigii*), mountain box (*Arctostaphylos uva-ursi*), Ethiopian pistachio (*Pistacia aethiopica*), and remnants of ancient juniper (*Juniperus*) forests. The high mountains of Yemen and Saudi Arabia also give shelter to a rich relict montane ecosystem. Coastal fog nearest the Red Sea creates a refugium for more than 170 endemic plants, and it is a critical refuge for a large number of endangered animals such as the Arabian leopard (*Panthera pardus nimr*) and the Hamadryas baboon (*Papio hamadryas*). On the Arabian Peninsula, the Al Hajar range forms a wall of mountains (< 3000 m) from the surrounding deserts, providing an important refuge for endemic and relict species of plants of Mediterranean and Indo-Iranian origin, often growing in the vicinity of tiyu (a carob relative) and other trees of African ancestry. The endemic Arabian tahr (*Arabitragus jayakari*), a type of wild goat, is still frequent in these precipitous slopes.

Along the Pacific coasts of Baja California, a fog refugium occurs where Mediterranean ecosystems give way to Sonoran Desert (Jennings et al., 2018; Vanderplank and Ezcurra, 2015; Vanderplank, 2013). Similar patterns can be seen in the extensive foggy deserts of Chile, particularly in the Copiapó region, for which the cactus *Copiapoa* is named. Some plants of the Chilean desert survive almost entirely on fog moisture, as do the desert camels or guanacos (*Lama guanicoe*) which are the famous inhabitants of the arid Atacama (Raedeke and Simonetti, 1988). The dunes of Namibia are home to many examples of tenebrionid beetle endemism. Species in the genus *Onymacris* have larvae that come to the surface at night and absorb water vapor through their rectal cavity, giving them unique adaptations to the most arid environments and allowing them to take advantage of fog moisture (Henschel and Seely, 2008).

Species Migrations and Biotic Considerations

Ackerly (2009a) introduces the concepts of synclimatic (with climate) migration, resulting in niche conservatism; and anticlimatic (not following climate) migration which often results in adaptive evolution. As such, species that moved with climate have conserved niches, species that did not move fast enough had to adapt. This of course results in ancient species that are very distinct (e.g., *Welwitschia* of the Namib desert), as well as more recently evolved desert endemics that have adapted on a climatic edge such as desert legumes that reach 60%–70% endemism in the central deserts of Baja California (Garcillan et al., 2010). Ackerly (2009a,b) points out that survival may be heavily dependent on biotic contexts and for those species not migrating with the climate it may be

the competition (or lack thereof) from new species arriving (or not) dictates whether a species survives the new regime (rather than it being wholly necessary to “adapt” to the new climate). In light of this, successful adaptive response may simply be driven by barriers to dispersal of other species.

Recent research on the biotic interactions between plants in the Tehuacan Valley has revealed that facilitation as a mutualism evolved between taxa from the quaternary (nurse plants) and taxa from the tertiary that were adapted to wetter conditions, but persist as a result of the nursing effects of more recently derived desert lineages (Valiente-Banuet et al., 2006). This is essentially a newer lineage (perhaps not endemic, certainly not rare) nurturing a paleoendemic in an inland desert. This facilitation prevented extinction during times of climatic change at the end of the tertiary, and facilitation is often provided by just a few keystone “nurse” species (Verdú and Valiente-Banuet, 2008). Surprisingly the generalist nurses are often the most abundant species in the community, providing strong resistance to extinction for the dependent species. These results indicate that biotic relationships between taxa not only have provided a mechanism for preserving biodiversity but also a mechanism for stabilizing selection through time (Valiente-Banuet et al., 2006). This facilitation also allows niche conservatism in ancient lineages and increases phylogenetic diversity in desert plant communities (Valiente-Banuet and Verdú, 2007). In closely related species, these facilitative mutualisms can turn into competition in times of stress of changing climate (Valiente-Banuet and Verdú, 2007; Verdú et al., 2010).

Rarity

Rarity is separate from endemism, a scarce plant having a wide range is essentially the complete opposite of a narrow endemic (i.e., endemics are not always rare, and vice versa), and this distinction relates to the differing habitats and distribution patterns of these plants (Mills and Schwartz, 2005). Kruckeberg and Rabinowitz (1985) give an excellent review of understanding of rarity and factors affecting narrow plant distributions, which are often considered the most threatened. There are seven broad types of rarity that vary with accordance to their degree of restriction, degree of habitat specificity, and local abundance—the most “rare” being both habitat specific and small range with a small population such as a species occupying an edaphic outcrop. Narrow endemics are most often members of distinctive communities or singular habitats, and as such, deserts are a rich breeding-ground for narrowly endemic species. An inability to exploit new habitats or to cope with anthropogenic change may be the most important general features associated with rarity (Cadotte and Lovett-Doust, 2002). Many desert species are considered “rare” simply because they are only seen above-ground following significant rainfall events—many ephemeral plants and geophytes, as well as several invertebrates which may only hatch *en masse* following specific climatic conditions. Scarcity is a dangerous strategy in arid environments since opportunities to reproduce are often highly restricted. Many animal species considered rare today in the world’s deserts have been pushed into this conservation status by anthropogenic impacts.

Desert Biogeography

Deserts are found throughout the world, and it is their biogeographic history that is critical to endemism and rarity. Deserts dominate in bands of arid land which run parallel to the equator, in both the northern and southern hemispheres, at 25–35 degrees latitude in each hemisphere (Fig. 1), forming the large, mid-latitude deserts approximately 2000–4000 km from the equatorial rainforests. In the northern hemisphere, the succession of mid-latitude subtropical deserts is formed by (1) the Nearctic, (3) the Palearctic, and (3) Indo-Malay. In the southern hemisphere, the chain is formed by (1) Neotropics, (2) the Afrotropics, and (3) the Australasian deserts (Allan et al., 1993; McGinnies et al., 1977; Pipes, 1998; Ricciuti, 1996).

Latitudinal Desert Belts

Solar radiation is highest nearest the equator, yet the tilt of earth’s axis (23.5 degrees) generates a zone of maximum solar interception that is to the north in the tropic of cancer half the year, and to the south in the tropic of Capricorn half the year. This creates a band of unstable air around the equator which in turn generates significant rainfall and is home to the equatorial rainforests. In the maximum solar interception regions (25–35 degrees north and south of the equator) the air is cooler and more stable, resulting in less precipitation, it is calm dry air that dominates. These are known as the “horse latitudes” and this is where our great deserts are located (Goudie and Wilkinson, 1977).

Continentality and Inland Deserts

Sometimes an arid desert is formed because of the enormity of a continental landmass. Atmospheric moisture comes primarily from the evaporation of our oceans and distance from the ocean can generate a considerable aridity gradient. As such, land-locked central areas of large continents may become deserts simply because the air reaching them is already dry. A good example of this is the Monte Desert in South America, as well as the Central Deserts of Australia and the Great Basin Desert of North America, but most especially in the Taklimakan and Gobi deserts of Central East Asia.

Fig. 1 The Desert Biome defined by three alternative criteria: (A) Arid regions of the planet as defined in the World Atlas of Desertification (UNEP, 1997); (B) global ecoregions of the world (Olson et al., 2001) that harbor desert vegetation; and (C) contiguous regions of extremely low vegetation cover derived from AVHRR satellite images of the world (USGS, 2005). The intensity of the red color indicates congruency between the three criteria: Areas in intense red correspond to regions where the three criteria coincide, areas in intermediate color highlight regions where two criteria coincide, and areas in pale red show areas where only one criterion operates.

Coastal Deserts and Fog Deserts

Despite the general latitudinal pattern of the world's deserts, only the western side of continents are normally occupied by deserts, while the eastern side tend to be more mesic. This is related to the circulation of our ocean currents. The pull is strongest at the equator that drives current to move in a clockwise direction in the northern hemisphere, and an anticlockwise direction in the southern hemisphere. As the surface waters move away from the continents, they pull cold, nutrient-rich water up to the surface, generating cool, stable air, often known as the "marine layer" or coastal fog. This very stable air can form some of the driest deserts on earth, such as the Atacama Desert, but also the Namib Desert, the Baja California Deserts, and the Coastal Desert of Morocco.

Rain Shadows and Tropical Deserts

Topographic considerations are also key to desert conditions. While the windward slopes of most tropical mountain ranges are covered by cloud forests, the leeward part, known as the "rain shadow" of the mountains, is covered by arid scrub. The rain shadow effect is largely responsible for many tropical arid lands that are found outside the mid-latitudinal ranges. Examples include the Sechura Desert in Peru and Ecuador, the Caatinga scrub in equatorial Brazil, or the Tehuacán Valley desert in southern Mexico, a hot-spot for cactus biodiversity. They are also responsible for some high-latitude cold deserts, such as Patagonia, and the deserts of Central Asia.

Desert Landforms

Deserts suffer much more wind erosion than any other environment. Additionally, if slopes are steep and when the rain does fall, they also experience very fast water erosion. Desert landscapes come in two categories: (1) "shield" deserts and (2) "mountain-and-basin" deserts (Cooke et al., 1992; Mabbutt, 1977) which alter their hydrology and carve their landscapes into new microhabitats for desert life.

Rainfall Pulses

Rainfall pulses are the central driving force structuring desert ecosystems and controlling the resource in highest demand. Plants and animals in desert regions have developed a plethora of adaptations to cope with the ephemeral abundance of water, in terms of their growth, population dynamics, and life cycles (Sher et al., 2004). Rainfall events often vary significantly from one pulse to the next, temporally (in terms of season), in size, intensity, duration, and dry interludes between pulses. Each desert organism is adapted to take advantage of these pulses, although often at different soil depths (triggered by different intensities and durations). Surface-

dweller are particularly excellent at taking advantage of brief and light pulses and endemism and rarity are seen in annual plants and short-lived (or *k*-selected) animals. More significant pulses sustain longer-lived species and the heterogeneity of pulses promotes species richness and biodiversity of desert ecosystems (Chesson et al., 2004). When rainfall is ample, desert annual wildflowers replenish their seedbanks, crustaceans, desert toads, and other amphibians reproduce exponentially before returning to their dry torpor, and granivorous rodents, such as North American kangaroo rats (*Dipodomys*), Australian hopping mice (*Notomys*), and African jerboas (*Jaculus*), can stock up their underground caches and larders, storing food for the long drought ahead.

Seasonality of rainfall pulses is extremely important and often affects which species are able to respond. Winter rainfall deserts tend to be found closer to Mediterranean and temperate ranges (higher latitudes) and summer rainfall deserts closer to the equator, with bimodal rainfall patterns in between. Seasonality affects which plants will germinate in bimodal deserts (Mulroy and Rundel, 1977). Unsurprisingly plants responding to winter rainfall tend to show more temperate affinities in their phylogeny and plants of summer rainfall have more tropical affinities. Plants that respond to winter rain are often faced with a very limited growth period because temperatures may not be conducive to the growth in winter months, and if they delay growth into the summer drought is imminent. This leaves just the spring months for plants to be productive, and as such, shifts the percentage of annual plants significantly up in the winter rainfall deserts (as compared to summer rainfall deserts). The rapid response of desert ephemerals often leads to highly synchronous blooms (including the famous “super-blooms” like that of 2019 in the California deserts). These plants survive dry periods (often many years of drought) as seeds or even in underground storage organs such as bulbs or tubers, and then must carry-out their life cycle very quickly in the short growing season. These species can afford to have aboveground structures that lack drought adaptation because they will be abscised or killed as the drought begins. As such, they can have large soft leaves and stomata, increasing their growth rate and providing significant resources to desert herbivores. Short generation times that dominate in desert environments are also subject to high evolutionary pressures and result in increased levels of speciation (Cutter and Gray, 2016). Monsoonal or summer rains, in contrast, provide water at a time when temperatures are ideal for plant growth and fast growth followed by a “hibernation period” which in plants results in drought-deciduousness as the dominant life-form and for animals an aestivation period (e.g., kangaroo rats and other members of the Heteromyidae). Fleshy trunks and extreme succulence are common in summer rainfall deserts, many of these plants having very shallow roots that cover a large surface area to capture even the slightest pulse.

Geographic Origins

The deserts of the world occur in six of the world’s large biogeographic domains, or eco-realms. A detailed description of each desert ecoregion within these realms can be found at National Geographic’s Wild World website (www.nationalgeographic.com/wildworld/terrestrial.html) and at the World Wildlife Fund’s terrestrial ecoregions website (<http://www.worldwildlife.org/science/ecoregions/biomes.cfm>). See further reading section for additional details (see EE papers) Enc Bio.

Afrotropic Realm: Deserts of East and Southern Africa

The Afrotropic deserts include four lowland desert ecoregions as well as eight coastal desert ecoregions including Arabia, Madagascar, Somalia, Namibia, and South Africa’s Succulent Karoo. They include 2.7 million square kilometers (10% protected), and they are home to charismatic macroflora such as *Welwitschia mirabilis*, with the greatest leaf longevity in the world, in the Namib desert, succulent-stemmed baobab trees (*Adansonia*), myrrh-trees (*Commiphora*), bottle-trees (*Pachypodium*), and kokerbooms (*Aloe dichotoma*). Southern Africa is home to 10% of the world’s flora, with 30% of the world’s fishmoths (Lepismatidae) are endemic therein. The deep red sands of the Arabian Desert are dominated by characteristic perennial plants such as *Calligonum comosum*, *Artemisia monosperma*, *Monsonia nivea*, and *Scrophularia deserti*; tussock grasses, *Panicum turgidum*, and other grasses are also abundant (Vesey-Fitzgerald, 1957). On the African continent, relictual species from wetter periods find refuge in the granitic inselbergs and ephemeral annual species dominate the dolerite ridges (Burke, 2003). Surprisingly the inselberg archipelago in the southern Namib Desert are not home to any endemic plant species, despite their aridity and isolation (Burke et al., 2002). However, high levels of endemism are found in plants, vertebrates, and invertebrates in Namibia’s escarpment region (Simmons et al., 1998).

The Succulent Karoo has three times as many endemics as the Sonoran Desert in one third of its area (Cowling et al., 1999), and is the world’s only plant biodiversity hotspot that is entirely found within the desert biome (Mittermeier et al., 1999) that boasts high levels of endemism for succulent plants, reptiles and invertebrates. The spatial isolation of rupicolous taxa (e.g., insects and reptiles) that are restricted to large coastal dune fields is hypothesized to have been key to speciation processes (Simmons et al., 1998). Areas of endemism and species richness in the succulent karoo do not overlap for mesic taxa, but show high overlap for succulent plants, insects, and arachnids (Simmons et al., 1998). Namaqualand is a winter-rainfall desert, with 40%–50% endemism in its flora, and narrow endemics in the northwestern parts of Namaqualand are significantly overrepresented in the Mesembryanthemaceae, Crassulaceae, and Asclepiadaceae (Cowling et al., 1999). Endemic plants are over-represented among succulent (dwarf and low) shrubs and, to a lesser extent, geophytes. Most endemic plant species in Namaqualand are neoendemics: mostly belonging to large genera and having many close relatives (Cowling et al., 1999). The Madagascan thorny desert thickets also have a unique and highly diverse flora and fauna, with high levels of localized endemism including the octopus tree (*Didierea madagascariensis*). The flora of Namibia includes at least 687 endemic plant species wholly within Namibia’s borders (17% of the flora), with two

centers of endemism therein: the Kaokoveld, and the Succulent Karoo. The Kaokoveld is home to 211 endemic species when the Angolan region is included, many of which are relics from the flora of northeast Africa. The succulent Karoo has around 380 endemic plants (including near-endemics) with high levels of recent speciation in the genus *Lithops* (Maggs et al., 1998).

Australasian Realm: Deserts of Australia

The deserts in the Australasian realm comprise 10 flat, lowland ecoregions in WWF's classification, covering some 3.6 million square kilometers (9% protected). All the arid eco-regions identified in Australia receive only sporadic rain and are sparsely vegetated. Endemism is particularly high in the mammals of the Australian deserts (excluding bats) (Keast, 1968). The Great Artesian Basin in central Australia has many desert springs that are home to very high levels of endemism in its amphipod populations (Murphy et al., 2013). Moisture-harvesting lizard the Australian thorny devil, *Moloch horridus*, (the only species in the genus, endemic to arid Western Australia) has special skin structures, comprising a micro-structured surface with capillary channels in between imbricate overlapping scales, which enable the lizard to collect water by capillarity and transport it to the mouth for ingestion (Comanns et al., 2016). The Gibson Desert, or stony desert is home to unique species such as the bloodwood or bleeding tree (*Corymbia opaca*), the mulga (*Acacia aneura*), and spinifex (*Triodia*) or Porcupine grass. Permanently wet areas for refugia and are home to a suite of relic-tual endemic ferns, reeds, and rushes. The Great Sandy-Tanami Desert is an extensive area of reddish sand plains (Ayers' Rock); while the Tirari Desert has vast sand dunes that harbor an abundant and diverse fauna, including locally endemic marsupials, lizards, frogs, and parrots.

Indo-Malay Realm: Deserts of India and Pakistan

The Indo-Malay region harbors two hot lowland deserts—the Indus Valley and the Thar—covering 0.26 million square kilometers (20% protected). The Thar desert is home to numerous species of reptiles, desert scorpions, mongoose (*Herpestes*), red fox (*Vulpes*), chinkara (*Gazella*), and falcons (*Falco*). Rare species such as the Indian Bustard, Blackbuck, and wild cat are disappearing in other parts of India but find refuge in the great desert. The area boasts 23 lizards and 25 different snakes. One of the most iconic species of conservation concern in the region is the Indian wild ass (*Equus hemionus khur*). The Thar desert is home to dominant plants such as *Halostachys caspica* on salty soils and *Aristida pennata* on sandy ones. Some of the endemic plant species of the Thar Desert are: *Caligonum polygonoides*, *Cenchrus biflorus*, *Acacia nilotica*, *Prosopis cineraria*, *Lasiurus indicus*, *Tecomella undulata*, *Citrullus colocynthis*, *Anogeissus pendula*, *Salvadora oleoides*, *Commiphora wightii*, *Haloxylon salicornicum*, *Capparis decidua*, *Suaeda fruticosa*, *Aerva pseudotomentosa*, *Crotalaria burhia*, and *Leptadenia pyrotechnica* (Khan et al., 2003). Around 45 plant species in the region are considered threatened or endangered (Khan et al., 2003). In the Indus Valley five large mammals are found: the Indian wolf, striped hyena, caracal, Indian leopard, and the urial (*Ovis orientalis punjabensis*) along with many rodents and other mammals. Meanwhile, the 190 species of bird in the desert include the red-necked falcon.

Nearctic Realm: Deserts of North America

The Nearctic deserts are formed by five lowland deserts including the Chihuahuan, Sonoran, and Mojave deserts and the coastal deserts of Baja California. They cover 1.7 million square kilometers (19% protected). The giant saguaro cactus (*Carnegiea gigantea*) is emblematic of the Sonoran Desert; and similar in appearance to the Cardón (*Pachycereus pringlei*) which dominates the Baja California deserts. The mostly arid peninsula of Baja California is home to more than 3500 species of plants, almost a quarter of which are endemic (Rebman et al., 2016). Major genera that dominate these deserts and exhibit high levels of endemism include *Agave*, *Fouquieria*, and *Bursera*. Around 1000 of the 3200 plant species in the Chihuahuan Desert are endemic. The Joshua tree (*Yucca brevifolia*) is the charismatic symbol of the Mojave Desert. Scorpion endemism is high in Baja California deserts, and very narrowly endemic desert pupfish are also found throughout the Nearctic deserts. Interestingly in the flora of Utah, most endemic plants are restricted to the low deserts of the state (Shultz, 1993). In California, Kraft et al. (2010) looked at the distribution of neoendemisms, which correlated poorly to climate and topography. They found the endemics of the western edge of deserts to be very young, with most endemism in habitats that have undergone post-pleistocene isolation or climatic change; with sky islands having wetter climates and the greatest temporal diversity of endemics.

Neotropic Realm: Deserts of South America

The Neotropic deserts include two lowland deserts a high-altitude inland desert (Central Andean Dry Puna), and the coastal deserts of Atacama and Sechura. They cover 1.1 million square kilometers (6% protected). These deserts form a long arid continuum that cover South America's "arid diagonal," starting from the Pacific Ocean in Peru, and running in a southeast direction to the Atlantic coast of northern Patagonia. The barren landscape of the Atacama Desert is one of the driest deserts on earth, sometimes going more than 20 years without rain (Armesto et al., 1993). On the coastal slopes above 600 m, plants and animals of the Atacama are entirely

dependent on the moisture provided by frequent fog (Armesto et al., 1993). However, on the coastal plains and canyons where fog is absent (between 26 and 30 degrees latitude), rainfall is the only moisture, and 40%–60% of the flora belongs to genera endemic to Chile (Armesto et al., 1993). The Monte, east of the Andes, is an open, low thorn-scrub harboring a characteristic endemic flora of zygophylls (family Zygophyllaceae). Many genera of invertebrates exhibit high endemism within the boundaries of the biogeographic province (Roig-Juñent et al., 2001). The Monte Desert is home to at least 180 endemic plants, mostly distributed in the most arid regions, with *Monttea aphylla* being endemic to the Monte and considered one of the species whose distribution most closely coincides with the proposed boundaries of the biogeographic province (Elías and Agesen, 2016). The dry Central Andean Puna carries tall tussocks of bunchgrass and a unique flora of high-altitude cushion plants.

Palaearctic Realm: Deserts of central Asia, the Middle East, and Northern Africa

The Palaearctic realm includes the largest set of deserts in the world including 21 lowland desert ecoregions that cover an immense corridor from the Atlantic coast of Morocco, to the Mediterranean coast of the Sahara, to the Gobi in Central Asia. The Palaearctic realm also harbors three coastal deserts (Atlantic Persian Gulf, and Red Sea), and in total covers 16 million square kilometers, 63% of all the deserts on the planet (9% protected). The great shield desert of the Sahara has immense dune fields for a third of its area. The deserts of sub-Saharan Africa show much more concentrated centers of endemism north of the equator, and the distribution of endemism bears no correlation to modern-day climate patterns (Linder, 2001). The deserts of the Middle East and Central Asia are all rain-shadow deserts, and the Sahara alone occupies 10% of the African continent. Vegetation is more diverse in the Western Sahara, with xerophytes and ephemeral plants in the open desert plains. Considering the hyper-arid conditions, the fauna of the Sahara is relatively rich, with 70 mammal species, 20 of them large; 90 species of resident birds, and around 100 species of reptiles. Central Asian Deserts are home to desert bulbs such as wild tulips (*Tulipa* spp.); and animals like wild Bactrian camels (*Camelus ferus*) and Asian wild asses (*Equus hemionus*). The Mesopotamian shrub desert is transitional between the deserts to the south and the steppes to the north. The whole eco-realm has evolved under continual grazing pressure and most plants are adapted to grazing pressure.

Convergence

The isolation of the great deserts of the different continents has driven outstanding examples of convergence, which are embodied by many examples from the arid-adapted plants (Figs. 2 and 3). Succulence, CAM (Crassulacean Acid Metabolism) photosynthesis,

Fig. 2 The Australian horny devils (*Moloch horridus*, shown in this picture taken in Alice Springs, Australia) are surprisingly similar the North American horned lizards (*Phrynosoma coronatum*, in Baja California) in both their feeding habits and their ecology. Their similarity, however, is due to convergent evolution in distant deserts, as they belong in different families and are taxonomically unrelated. Photo credits: Patricio Robles-Gil.

Fig. 3 Evolutionary convergence in desert plants' life-forms from different evolutionary origins. (1) *Sarcocaulouscent* (giant-stemmed) trees: (A) Baobab trees (*Adansonia digitata*, Malvaceae) in the Bandia Reserve, Senegal and (B) Elephant tree (*Bursera microphylla*, Burseraceae) in Baja California, Mexico. (2) *Succulent-leaved rosettes*: (C) Socotrine aloe (*Aloe perryi*, Asphodelaceae) in the island of Socotra, Yemen, and (D) desert agave (*Agave deserti*, Agavaceae) in Palm Canyon, California. (3) *Crassicaulescent* (succulent-stemmed) growth forms: (E) Candelabra tree (*Euphorbia candelabrum*, Euphorbiaceae) in Northern Tanzania, and (F) Senita cactus (*Pachycereus schottii*, Cactaceae) near La Paz, Baja California Sur, Mexico. (A) From Myriam Louviot Wikimedia Commons id = 2,717,945. (B) From Dick Culbert, Wikimedia Commons id = 50,051,571. (C) From Gerry & Bonni, Wikimedia Commons id = 38,582,139. (D) From Stan Shebs, Wikimedia Commons id = 195,444. (E) From Amante Darmanin, Wikimedia Commons id = 42,133,155.

and drought adaptations have evolved multiple times in these discreet regions. For example, cacti (Cactaceae) and euphorbs (Euphorbiaceae) have evolved very similar suites of characters, including spines, succulent bodies, leaflessness or highly ephemeral leaves, slow growth rates, high longevity, CAM photosynthesis and the presence of bumps on their surface. Convergence is also seen between different members of the Cactaceae such as the *Mammillaria* species of North American and the *Gymnocalycium* of South America. The family Aizoaceae, predominantly African in origin, including the living stones (*Lithops*) consists of succulents that bare remarkable resemblance to many of the Crassulaceae, primarily found in the Americas (e.g., stonecrops and *Sedum* species). Even woody-stemmed spiny shrubs can be seen to converge when we compare *Fouquieria* (Fouquieriaceae) from the Sonoran Desert with and *Didierea* (Didiereaceae) from Madagascar. Stem-succulent trees are a distinctive feature of tropical drylands. In addition to their water storage capacity, they often have photosynthetic bark, which can process internally respired CO₂ with almost no water loss at

all (Ávila-Lovera and Ezcurra, 2016). These trees include the Baobab (*Adansonia*) from Africa, and the *Burseras* of central America and the Caribbean. Other non-succulent trees with green photosynthetic stems include many of the legumes of the Baja California deserts (e.g., *Parkinsonia*), as well as *Colletia* from Argentina and South American deserts. Similar processes have occurred in the fauna, one example being the similarities between the hares or jackrabbits (*Lepus californicus*) of North America and the bilby (*Macrotis lagotis*), an endangered marsupial similar to a jackrabbit, with giant ears for temperature control in Australia. In 1976, Blair assessed convergence across vertebrates between the Monte Desert (Argentina) and the Sonoran Desert (USA). He found very low endemism in amphibians, but higher in reptiles. Highest of all are the levels of endemism in desert heterotherms (vertebrates which can control and adjust their body temperature), which reach 71% in the Monte and 61% in the Sonoran Desert (excluding Baja California). Mammals in contrast exhibit very low levels of endemism in both regions, and although the mammal fauna of Sonoran deserts is double that of the Monte, it has lower rates of endemism (Blair et al., 1976). *Ariocarpus agavoides* in Tamaulipas looks a lot like the rosetofilous agaves of central Mexico and there are almost endless examples of uniquely evolved taxa from distinct origins, sharing very similar morphologies and adaptations. Recent research indicates that convergence and trait conservatism can be very difficult to separate and are highly dependent on temporal scale (Ackerly, 2009a; Ackerly et al., 2010). Some examples of convergence can be seen in the disparate deserts of the world, yet in contrast to the high levels of endemism in many desert plants around the world, desert vines are surprisingly pantropical and the genera shared between the major deserts (Parsons, 2005).

Conclusion

Diverse processes have affected the evolution and origin of the incredible biodiversity of the world's deserts. The formation of the deserts themselves, climatic change through deep time, and biotic interactions have all shaped the biodiversity patterns that we see today, resulting in hotspots of endemic taxa which may be young or old, or both. These processes have resulted in key conservation targets, both in the deserts themselves, and the unique species found therein. Despite similar climatic conditions, isolation has resulted in the evolution of many similar life forms with highly divergent origins in arid lands around the globe. While deserts and their inhabitants may sometimes look similar, each represents a unique series of adaptations and an original solution to our shared challenge of life on planet earth. Excellent stewardship of our global deserts is essential to biodiversity conservation and the survival of many highly evolved plants and animals.

Abstract

The common perception of the Desert biome is that it generally constitutes remote areas of low diversity. However, the world's largest warm desert, the Sahara, together with the neighboring arid Sahel exhibit high topographic and climate heterogeneity and have experienced strong climatic oscillations that have shaped land-cover and biodiversity distribution. This review summarizes the knowledge on the Sahara-Sahel biodiversity patterns based on the distribution of terrestrial vertebrate species richness (also called α -diversity) and species turnover or the change in species among sites (β -diversity). The distribution of β -diversity in the Sahara-Sahel follows the general latitudinal gradient, with higher percentage of species found in the southern Sahel region. This broad latitudinal gradient pattern is disrupted by higher number of species distributed along hypothesized ecological corridors and refugia. The distribution of β -diversity highlights the boundaries of the Sahara-Sahel hotspots of species richness. At local scale, recent studies have emphasized the natural value of isolated and residual wetlands (oases, lakes, and seasonal rivers) of high productivity, acting as refugia for relict populations. Among these wetlands, mountain rock-pools constitute local hotspots of biodiversity.

Introduction

Desert biomes are generally perceived as remote and uniform areas of low diversity when compared to other biomes. Yet they host unique assemblages of species, communities and ecological processes (Ward, 2016). Desert biomes exhibit high local diversity, often endemics, largely because organisms are capable of exploiting patches of high productivity (Ward, 2016). Deserts constitute perfect laboratories for biogeographic studies as species and communities are highly structured and are subject to strong climate control (Ward, 2016). In North Africa, the Sahara Desert and the arid Sahel exhibit unique features that distinguish them from other warm deserts and arid regions worldwide, which make them suitable for observing and understanding biogeographic patterns.

The Sahara is the largest warm desert in the world with land coverage of about 9 million km², and together with the arid region Sahel, they cover about 11 million km² (Fig. 1). Despite its large extent, the Sahara was recently formed. Evidences pointed for about 7 million years ago in Chad (Schuster et al., 2006; Zhang et al., 2014) or even more recently (2–3 million years ago) in western regions (Swezey, 2009). Around 7 million years ago, the African tectonic plate crashed relative to the Eurasian plate and the resulting closure of the Tethys Sea (the forerunner of the modern Mediterranean Sea) was associated with the earlier aridification of the Sahara Desert (Zhang et al., 2014). Since the Pliocene (5.3–2.5 Mya), the region experienced strong climatic oscillations with multiple dry-wet cycles (Le Houérou, 1997). For instance, around the mid-Holocene, the region experienced the last humid period being covered with extensive grassland vegetation, lakes and wetlands (Gasse, 2000; Kröpelin et al., 2008). This wet period finished between 6 and 5000 years ago with an increase of aridity, disappearance of mesic vegetation communities, decreased of lake levels, and the current onset of conditions were established (Foley et al., 2003; Holmes, 2008). The climate and land-cover oscillations have greatly shifted the limit between the Sahara and the Sahel with profound effects in the distribution of biodiversity patterns (Brito et al., 2014, and references within).

The Sahara-Sahel is characterized by high topographic heterogeneity, from salt pans below sea level to high-altitude peaks distributed along a system of mountains (UNEP, 2006; Fig. 1). The region displays strong environmental gradient and heterogeneity, mostly arranged in a latitudinal way (Fig. 2). There is considerable spatial variability in average annual temperature (from 8°C to 30.8°C) and precipitation (up to 1432 mm). The current location of the border between the Sahara and the Sahel overlaps with a biogeographic crossroad between the Palaearctic and Afro-tropical biogeographic realms (Dinerstein et al., 2017; Fig. 1), and with a transition zone between two major biomes—Deserts and Xeric Shrublands and Tropical and subtropical grasslands, savannas, and shrublands (Fig. 2). This biogeographic location resulted in a latitudinal variation in species distribution and increased local biodiversity (Brito et al., 2014, and references therein). Given the biogeographic location, the Sahara-Sahel is a perfect example of an area of high species replacement, holding a geographically structured assemblage of species, natural communities, and environmental conditions (Ecoregions, Dinerstein et al., 2017). Thus, it is highly suitable for studying biogeographic patterns. In this

Fig. 1 The Sahara-Sahel. Limits of the Sahara-Sahel (Dinerstein et al., 2017), altitudinal variation, and distribution of protected areas. SEN: Senegal; BFA: Burkina-Faso; NGA: Nigeria; CMR: Cameroon; CAR: Central African Republic; ETH: Ethiopia; ERI: Eritrea.

context, uncovering distribution patterns of spatial structure of biodiversity focusing local species richness (also called α -diversity), species turnover, i.e., change in species among sites (β -diversity), and regional species diversity (γ -diversity) are fundamental for understanding the biogeography of the region. This chapter describes the major biogeographic patterns of biodiversity in the Sahara-Sahel region, focusing in these major components of diversity.

Biodiversity Distribution Patterns

The knowledge about biodiversity distribution patterns across the Sahara-Sahel is still poorly documented in comparison to other biomes, despite the increasing sampling efforts over the last decades (Brito et al., 2014, 2016). The geographic location in countries of low human development has hampered the allocation of funds for scientific studies (Durant et al., 2012; Brito et al., 2014). Moreover, field surveys and trans-border research has been also obstructed by the regional insecurity and armed conflicts (Brito et al., 2018). These constraints result in a large number of species whose knowledge on geographic distribution, population status and demographic trends are insufficient or lacking for assessing conservation status. For instance, ~17% of the Sahara-Sahel terrestrial endemics remain unevaluated (NE) and 15% are data deficient (DD) according to IUCN Red List (2018). Due to general remoteness and insecurity, large portions remain poorly surveyed and unexplored, such as northern-eastern Mauritania, northern Mali, south-western Algeria, or southern Libya (Brito et al., 2014).

From the available data about distribution patterns of terrestrial vertebrates (amphibians, reptiles, birds and mammals), the Sahara-Sahel biodiversity is spatially well-structured (Fig. 3). Overall, biodiversity distribution (α -diversity) in the Sahara-Sahel follows one of the oldest patterns in ecology and biogeography: the latitudinal diversity gradient (Brown and Lomolino, 1998). Thus, there is a latitudinal gradient in species richness, with high number of species restricted to the southern Sahel, followed by the lower Nile valley. The latitudinal distribution patterns are consistent with the distribution of biogroups, i.e., species assemblages with shared distributions, and functional groups, i.e., species assemblages with shared biological traits (Vale and Brito, 2015; Brito et al., 2016).

The broad latitudinal gradient is however disrupted by high percentage of species restricted to the central Sahara mountains and along the Nile river valley (Fig. 3). Furthermore, high levels of biodiversity are also distributed along rivers, and hypothesized ecological corridors and refugia in the Sahara-Sahel (Brito et al., 2014, and references within). For example, the coastal belt of the Atlantic Sahara, the mountains of the central Sahara, the Red Sea coast, and the Nile River valley are pointed as ecological corridors for terrestrial vertebrates (Brito et al., 2014). They follow North-South axis and are remnants of savannah-like habitats that covered the region during past humid periods (Brito et al., 2014). The mild climate influenced by the proximity of the sea in the Atlantic Sahara and Red Sea corridors also contribute to local high species richness (Brito et al., 2014; Gonçalves et al., 2018; Velo-Antón et al., 2018). Continental mountains support high α -diversity of endemic terrestrial vertebrate species, as well as a relatively high diversity of Afrotropical fishes and flora (Brito et al., 2014, and references within). Due to their geographic or environmental isolation, Sahara-Sahel mountains constitute refugia for biodiversity, particularly for aquatic and mesic species (Brito et al., 2014, 2016; Gonçalves et al., 2018 and references therein). Species with distinct biogeographic affinities are currently found in isolated suitable habitats, suggesting temporal distribution shifts during Plio-Pleistocene cycles (Dumont, 1982; Le Houérou, 1997; Drake et al., 2011) and former population connectivity during favorable conditions (Dumont, 1982; Drake et al., 2011).

Fig. 2 Environmental variability in Sahara-Sahel derived by spatial principal component analysis (SPCA). *Top*: Composite map of current climate variability, where PC1 in red (52.5%): temperature seasonality (standard deviation $\times 100$), and temperature annual range; PC2 in green (24.5%): maximum temperature of warmest month and mean temperature of warmest quarter; and PC3 in blue (10.3%): annual mean temperature, minimum temperature of coldest month and precipitation of wettest month. *Bottom*: Composite map of land cover variability, where PC1 in red (43.3%): distance to open broadleaved deciduous forest/woodland, shrubland and herbaceous vegetation and grassland; PC2 in green (15%): distance to cropland, mosaic cropland and sparse vegetation or grassland and PC3 in blue (11%): distance to bare, rock and sandy areas.

The distribution of β -diversity in terrestrial vertebrates tends to disrupt the broad latitudinal gradient pattern observed for α -diversity (Fig. 3). While the hypothesized ecological corridors and refugia are identified by α -diversity patterns (i.e., high number of species observed), β -diversity highlights the boundaries within the Sahara-Sahel hotspots of species richness. High turnover is expected in transition areas between high and low species richness, and also abrupt shifts in assemblage composition. There is some overlap in the transition area between the Palaearctic and Afro-Tropical realms (Dinerstein et al., 2017) and high β -diversity, which reveals a turnover in species composition and richness in the area. High β -diversity of total species depicts the edge of hypothesized ecological corridors and refugia, such as the Atlantic Sahara, the Central Sahara mountains, the Red Sea coastal mountains, and the Nile river valley. The β -diversity in endemics, besides defining as well these ecological corridors and refugia, also highlights the vast empty quarters and dune massifs with low β -diversity values and overall low species diversity (Brito et al., 2014; Vale and Brito, 2015). The Sahara-Sahel mountains hold high levels of endemics, probably resulting from the refugia character of mountains during past climatic oscillations (Trape, 2009; Brito et al., 2014). Due to the mild conditions and high productivity, the Atlantic and the Red Sea coastal areas and the Nile river valley also hold high levels of Sahara-Sahel endemics (Brito et al., 2014, and references within).

The distribution of β -diversity patterns is inconsistent among taxonomic groups (Fig. 3). For instance, there are no amphibian communities in the deepest Sahara, due to generalized lack of water availability. The β -diversity patterns in reptiles are similar to those observed for mammals, particularly within the Sahara. Similarity is also observed to endemics, as most of endemic species of the Sahara-Sahel are constituted by reptiles and mammals (Fig. 3). Endemic lizards were located in the most arid and flat areas of the Sahara-Sahel (Vale and Brito, 2015). In birds, β -diversity follows different patterns and highlights the major migratory routes,

Fig. 3 Biodiversity distribution patterns of terrestrial vertebrates (amphibians, reptiles, birds and mammals) in the Sahara-Sahel. α -Diversity and β -diversity for total number of species and endemics, and β -diversity by taxonomic group. Species distribution polygons were retrieved from IUCN (2018). β -Diversity was quantified using the Simpson measure (β sim) which account for pure spatial species turnover (Baselga, 2010).

across the Libyan desert and following Western Nile river valley (Somveille et al., 2019). β -Diversity in mammals tends to follow the patterns observed for reptiles and endemics, highlighting the vast empty-quarters as important for small mammals (Vale and Brito, 2015) and for large-sized vertebrates, such as *Acinonyx jubatus*, *Addax nasomaculatus*, or *Chlamydotis undulata* (Brito et al., 2014, and references within).

At the local scale, isolated and residual wetlands (oases, lakes and seasonal rivers) surrounded by sandy areas act as refugia for relict populations and constitute suitable habitats where unique species have evolved (Brito et al., 2014, and references within, Trape, 2013). High levels of local diversity are found restricted to these humid habitats within corridors, such as the Atlantic Sahara-Sahel and mountain refugia. Located in the upstream of narrow valleys at the base of these mountains, mountain rock pools (locally known as *gueltas*) constitute micro-wetlands that allow the maintenance of rich communities, with many endemic species, and relict Afro-tropical fauna (Vale et al., 2015; Brito et al., 2014, and references within). A study of 69 *gueltas* (total area of about 43 ha) highlighted their natural value as local hotspots of biodiversity, since they hold about 32% and 78% of the total taxa analyzed and endemics of Mauritania, respectively (Vale et al., 2015). The number of species present in *gueltas* was found to be positively correlated with primary productivity, area of *gueltas*, and occurrence of permanent water (Vale et al., 2015). Studies in the Atlantic

Sahara corridor emphasized the existence of a network of seasonal rivers that acted as dispersal corridors. For example, these corridors allow gene flow between isolated populations of West African crocodile (*Crocodylus suchus*) in the mountains of Mauritania and southern populations in Mali and Senegal (Velo-Antón et al., 2014). The value of wetlands across the Sahara as refugia for relict tropical fauna is emphasized by the presence of these crocodiles, which persist as relict populations in Chad and Mauritania (Brito et al., 2014, and references within).

In the last decade, and despite the growing regional insecurity, increasing scientific efforts allowed the consolation of the Sahara-Sahel as natural laboratory for understanding biogeographic patterns. Insights on biodiversity distribution have emerged from increasing sampling effort of taxa and multidisciplinary scientific studies. The Sahara-Sahel is a perfect model to understand the effects of extreme climatic events on biodiversity distribution. The past climatic oscillations in the region have left an obvious signature in the distribution of alpha and beta diversity. Locally, small wetlands act as refugia for relict populations and constitute places where unique species evolve, constituting hotspots of biodiversity. The biogeographic patterns currently observed may provide also indications on potential outcomes of increasing aridity.

The conservation of Sahara-Sahel biodiversity has been yet neglected and overlooked by global assessments (Brito et al., 2014, 2016, 2018). The predicted increasing aridity associated with the escalating conflicts and social insecurity is expected to accelerate biodiversity decline (Brito et al., 2014, 2016, 2018; Vale and Brito, 2015). Desert adapted species living mostly in flat areas, where the predicted magnitude and velocity of climate change are higher, are the most vulnerable ones (Vale and Brito, 2015). Among those are the Sahara-Sahel iconic mega-fauna that have been experienced recent continuous decline due to unsustainable hunting pressure (Brito et al., 2018). Despite the design of protected areas outside areas of human activities, they are clearly insufficient and inefficient as they cross multiple political borders, requiring internationally coordinated efforts for implementation and management (Brito et al., 2016). This is particularly challenging as Sahara-Sahel range countries are developing nations, most ranked as Low Human Development and are largely underfunded for biodiversity conservation (Brito et al., 2018 and references within). As such, strategies for regional and optimized biodiversity conservation are still in need of development in the Sahara-Sahel. For instance, conservation efforts should engage from local governments to local communities in the safeguard of seasonal wetlands that sustain both human communities as well as biodiversity. Conservation actions and programs linking poverty reduction with biodiversity conservation are also in need of development. Increasing local awareness and pride within communities of the value and uniqueness of the Sahara-Sahel wildlife should be one of the first actions. Such approach would allow including biodiversity conservation and awareness into resilient peace strategies, under penalty of any other conservation measure failure (Brito et al., 2018).

Abstract

The Great Basin of the western United States is the largest cold desert in North America. The region is most commonly defined by its hydrology, delineating an area more than 300,000 km² in size with no natural outlet to the ocean. This vast expanse of the North American interior west is dominated by the variable topography of the Basin and Range geologic province and encompasses a broad spectrum of both arid and semi-arid plants and animals. The Northern terminus of this closed basin system lies in the high desert ecological province of southeast Oregon. One of the healthiest and most intact ecosystems within the Great Basin, the Northern Great Basin boasts a fascinating diversity of native plant and animal communities and is a worldwide exemplar of the sagebrush steppe ecosystem. The biotic and abiotic components of this region make it a useful case study to examine the biodiversity of the high desert biome in North America. Here we discuss the role of geology in establishing the present day Northern Great Basin, the major plant communities and terrestrial vertebrates found there, and threats facing the region's natural systems.

The High Desert Biome

The Great Basin

The Great Basin of western North America contains some of the most topographically fragmented landscapes on the planet (Badgley et al., 2014). Characterized by the dramatic physiography of the Basin and Range geologic province, with broad temperature and elevation gradients (Chambers and Wisdom, 2009), the region supports a surprising diversity of arid and semi-arid flora and fauna, including some of North America's most recognizable species.

Defining the Great Basin's boundaries has traditionally depended on one of three sets of attributes—the region's flora, hydrology, or geology. The most common definition delineates a hydrographic region that sits between the Sierra Nevada and Cascade mountain ranges on the west, and the Rocky Mountains on the east (Fig. 1). Composed of a series of contiguous watersheds, the Great Basin spans over 300,000 km² across six western states and has no natural outlet to the ocean (Grayson, 2011).

Annual precipitation ranges widely from an average of approximately 5 cm in the lowest basin in Death Valley, California to over 100 cm on the high peaks of the Wasatch Mountains in Utah. The combination of dramatic shifts in both elevation and interannual

Fig. 1 The hydrographic Great Basin. Data sources: [USGS](#); [NOAA](#).

precipitation has played a critical role in shaping the ecology of the region and has produced a mixed composition of both grassland and desert species ([West, 1999](#)).

The Northern Great Basin

In the far northern reaches of the Great Basin lies the high desert ecological province of southeastern Oregon ([Anderson et al., 1998](#)). As with the larger Great Basin, this landscape is dominated by a series of north-south oriented fault block mountains separated by lowland basins ([Franklin and Dyness, 1988](#)), ranging in elevations from 1250 to 2965 m. Annual precipitation averages 25 cm across the region, fluctuating nearly 100 cm between the lowest basins and highest ranges ([Anderson et al., 1998](#)). Low and high temperatures during the growing season average 1°C and 20°C respectively ([Anderson et al., 1998](#)) and can vary dramatically throughout the year from extreme lows of −30°C to over 40°C during summer months.

We define the focal area of this paper as the northern portion of the hydrologic Great Basin in southeast Oregon, henceforth referred to as the Northern Great Basin ([Fig. 2](#)). The diversity of life and landform in this region provides a useful case study to examine the geology, plant communities and major classes of wildlife that inhabit the high desert biome of western North America.

Fig. 2 The Northern Great Basin. Data Sources: [USGS](#); [NOAA](#).

Geology

The geologic processes behind the Northern Great Basin's most prominent features have played a foundational role in shaping the region's biodiversity. Two major processes, volcanism and faulting, and how they have interacted with climate, are major drivers in landform development across the region. The resulting landscape creates a unique set of systems where diverse communities of organisms interact.

Geologic Provinces

The Northern Great Basin overlaps with three geologic provinces of Oregon: the High Lava Plains, Basin and Range, and the Owyhee Upland (**Fig. 3**). These provinces are located east of the Cascade mountain range, which blocks moist air from the Pacific Ocean and contributes to the region's arid climate. The High Lava Plains and Owyhee Upland provinces consist of mostly flat-lying volcanic deposits that give this part of the region its characteristic topography of vast, rolling plains of grasslands and sagebrush. The Basin and Range province, which dominates the Northern Great Basin, is the northwest extent of the much larger Basin and Range physiographic region that extends throughout much of the Great Basin and interior western United States. The Basin and Range is characterized by numerous, roughly parallel mountain ranges separated by flat valleys, or basins (**Fig. 4**). This topography creates abrupt changes in elevation over very short distances, resulting in arid desert valleys immediately adjacent to steep mountainous terrain. Each of these geologic provinces shares a similar geologic history that has been shaped by volcanic activity and faulting.

Volcanism

The Northern Great Basin is among the most active volcanic regions in the western United States. Nearly all of the rocks exposed in the region are volcanic in origin and geologically very young, ranging in age from about 17 million years old to just a few 1000 years old (**Fig. 3**). Between about 17 and 14 million years ago, massive eruptions of flood basalts occurred from numerous vents in

Fig. 3 Geologic provinces of Oregon (modified from Miller, M.B. (2014). *Roadside Geology of Oregon*. Missoula, MT: Mountain Press Publishing Company), volcanic deposits from ~17 million years ago to present (modified from Smith, R.L. and Luedke, R.G. (1984). Potentially Active Volcanic lineaments and loci in western conterminous United States. In: *Explosive Volcanism: Inception, Evolution, and Hazards*, 47–66), and Oregon faults. Data Sources: USGS; NOAA; Oregon Explorer.

a north-south alignment from northern Nevada to southeastern Washington (e.g., Zoback et al., 1994; Carlson and Hart, 1987; Hooper, 1997). The largest volumes of basalt erupted in the northern portions of this region, including the Columbia River Basalts (e.g., Tolan et al., 1989) and the Steens Basalts (e.g., Carlson and Hart, 1987) which together cover large portions of the Northern Great Basin. Near the southern boundary of the Northern Great Basin, eruptions of flood basalts were accompanied by large, highly explosive caldera-forming eruptions that produced silicic volcanic centers similar to those along the Snake River Plain in Idaho and the Yellowstone area (e.g., Conrad, 1984; Rytuba and McKee, 1984; Ekren et al., 1982). From about 14 million years ago to the present, volcanic activity has continued, creating numerous volcanic centers and lava flows (e.g., Hart et al., 1984; Jordan et al., 2004). Many of these young volcanic deposits and flows lack significant vegetation and soil development, creating stark volcanic landscapes that offer unique microclimates and habitats.

Fault Systems

In addition to active volcanism, the Northern Great Basin is also characterized by geologically young fault systems. These faults are caused by extension of the Earth's crust, which in turn is caused by the global forces of plate tectonics. Many of these faults were active prior to and concurrent with volcanic activity, offsetting the volcanic rocks described above. In the Northern Great Basin, fault systems trend northwest and north-northeast (Fig. 3). The north-northeast trending faults are part of the larger Basin and Range province and are tens of kilometers long and have offset the earth's surface by hundreds of meters to several kilometers (e.g., Donath, 1962; Walker and MacLeod, 1991; Pezzopane and Weldon, 1993; Crider, 2001). It is estimated that Basin and Range extension has stretched the Northern Great Basin by about 17% during the last 15 million years (Wells and Heller, 1988). In contrast to the north-northeast trending faults in the Basin and Range province, the High Lava Plains province is dominated by northwest trending faults. These occur as hundreds of short, parallel fault systems that cover a wide zone called the Brothers Fault Zone. These faults are a few kilometers long at most and have offset the surface by only a few tens of meters (e.g., Lawrence, 1976; Walker and

Fig. 4 Basin and range topography in the Northern Great Basin. Source: Photo by Jim Davis.

MacLeod, 1991). Short, northwest trending faults like those of the Brothers Fault Zone also occur within, and are contemporaneous with, the larger north-northeast trending faults of the Northern Great Basin's Basin and Range province (e.g., Crider, 2001; Donath, 1962; Pezzopane and Weldon, 1993). The contrast between the flat or rolling topography of the High Lava Plains province and the high relief of the Basin and Range province is in part a result of these two types of faults; shorter faults with less offset have created the subdued topography of the High Lava Plains, which grades southward into the steep mountain ranges and valleys created by longer faults with more offset.

Climate

During the last 2 million years changes in Earth's climate caused multiple ice ages, or glacial periods. During these periods, increased precipitation filled the enclosed valleys of the Northern Great Basin's Basin and Range, creating large lakes (e.g., Snyder et al., 1964; Orme, 2008). At the highest elevations, alpine glaciers formed and carved glacial cirques, arêtes, and U-shaped valleys in the layers of volcanic rock uplifted by Basin and Range faulting (e.g., Smith, 1927; Evans and Geisler, 2010). About 12,000 years ago the most recent glacial period ended as the climate became warmer and drier. Alpine glaciers disappeared and the extensive lakes throughout the Northern Great Basin evaporated, leaving behind much smaller, shallow alkaline lakes and dry playas common in the region today.

Plant Communities of the Northern Great Basin

The Northern Great Basin contains some of the most intact sagebrush steppe plant communities in North America (Connelly et al., 2004). Millions of acres of sagebrush cover the landscape providing critical habitat for species such as the greater sage-grouse (*Centrocercus urophasianus*), pygmy rabbit (*Brachylagus idahoensis*) and the Great Basin spadefoot toad (*Spea intermontana*). Within this shrub dominated expanse, several other notable plant communities contribute important roles to the regional ecology, including salt desert scrub, riparian area, and tree communities, often following elevation and edaphic changes (Shreve, 1942) (Fig. 5). Each of these plant communities has unique attributes and qualities that, in combination, contribute to the Northern Great Basin's diverse assemblage of life (Miller and Eddleman, 2000).

Sagebrush Steppe

The sagebrush steppe of the Northern Great Basin is defined by its high elevation shrub communities, hot dry summers, and cold wet winters (Miller and Eddleman, 2000; Pyke et al., 2015; West, 1999). Sagebrush (*Artemisia* spp.) are the dominate shrubs of the region and a keystone species, occurring across an array of ecological conditions (Fig. 6). There are over 20 species and subspecies of woody sagebrush, with 12 commonly found in the Northern Great Basin (Winward, 1980; Shreve, 1942). Of these, big sagebrush

Fig. 5 Plant communities in the Northern Great Basin. Data Sources: USGS; NOAA; The Habitat Institute.

(*Artemisia tridentata*) and low sagebrush (*Artemisia arbuscula*) commonly occur and frame much of the ecology (Winward, 1980; Franklin and Dyrness, 1988; Miller and Eddleman, 2000). Numerous other shrub species are common within the sagebrush steppe, most notably rabbitbrush (*Chrysothamnus* spp.) and bitterbrush (*Purshia tridentata*) (Franklin and Dyrness, 1988).

Big sagebrush is the most widespread sagebrush species in the Northern Great Basin, with three commonly recognized subspecies (Winward, 1980). Of these subspecies, Wyoming big sagebrush (*Artemisia tridentata wyomingensis*) and mountain big sagebrush (*Artemisia tridentata vaseyana*) dominate, providing important wildlife habitat across the region from the edge of the lowland alkali flats to the high montane woodlands (Dealy et al., 1981; Miller and Eddleman, 2000; Pyke et al., 2015).

Wyoming big sagebrush is typical of more arid sites, generally below 1800 m, and is the most prominent of the big sagebrush subspecies (Winward, 1980). As a more drought tolerant sagebrush, it tends to support a lower abundance of understory plants, most notably forb species, when compared to mountain big sagebrush (Winward, 1980; Davies and Bates, 2010). In contrast, mountain big sagebrush generally occupies higher elevation foothills and mountain slopes between 1050 and 3000 m (Winward, 1980) where soils are deeper and moisture persists for longer periods throughout the year (Davies and Bates, 2010; Winward, 1980). The environmental conditions of these sites make mountain big sagebrush communities more productive (Davies and Bates, 2010; Winward, 1980), with it not uncommon to find several dozen species of forb in the understory (Miller and Eddleman, 2000; Winward, 1980). Big sagebrush communities play an essential role in the life histories of regional wildlife, constituting an important food source and creating essential cover for hiding and thermal refugia. The plant's evergreen leaves and year-round availability

Fig. 6 The sagebrush steppe in the Northern Great Basin. Sources: Photo by Jim Davis.

of crude protein make it valuable winter forage for numerous wildlife species, including the greater sage-grouse, mule deer and pronghorn (Welch and McArthur, 1979).

Low sagebrush, while not as common as big sagebrush, is found consistently throughout the Northern Great Basin between 1000 and 3300 m (Winward, 1980). It prefers areas with shallow, stony soils with poor drainage, often overlaying unfractured bedrock or an impermeable substrate (Franklin and Dyrness, 1988; Winward, 1980). Low sagebrush communities constitute important seasonal food sources for foraging wildlife, especially in the spring due to the early emergence of forage species (grasses and forbs) relative to surrounding plant communities (Dealy et al., 1981).

Understory

The native understory of the sagebrush steppe is a dynamic composition of perennial bunchgrasses, forbs, and biological soil crust (Miller and Eddleman, 2000). Depending on a variety of factors, the ratio between forbs, perennial grasses and shrubs can vary widely (Pyke et al., 2015).

Perennial bunchgrasses form the dominant component of the herbaceous understory and include species such as: bluebunch wheatgrass (*Pseudoroegneria spicata*), needle-and-thread grass (*Hesperostipa comata*), Thurber's needlegrass (*Achnatherum thurberianum*), Idaho fescue (*Festuca idahoensis*), bottlebrush squirreltail (*Elymus elymoides*), and Sandberg bluegrass (*Poa secunda*) (Dealy et al., 1981; Franklin and Dyrness, 1988; Winward, 1980). Forbs are a smaller percentage of the ground cover, however they display a far greater diversity with over 200 species having been documented in the sagebrush steppe (Miller and Eddleman, 2000; Miller et al., 2000). Biological soil crust, while sometimes overlooked, is a critical component of the sagebrush steppe understory. A complex mix of organisms including lichen, algae, fungi and cyanobacteria (Ponzetti and McCune, 2001), biological soil crust helps prevent soil erosion and establishment of non-native species, and contributes nitrogen and other minerals to adjacent plant species (Ponzetti and McCune, 2001).

Salt Desert Scrub

Salt desert scrub is characterized by halophytic plant communities that are well adapted to the lowland dry lake beds and alkali flats of the region's basins (Comstock and Ehleringer, 1992; Franklin and Dyrness, 1988). The saline soils of these sites create an environment that limits the presence of sagebrush, giving way to two other dominant shrub communities, shadscale (*Atriplex confertifolia*) and greasewood (*Sarcobatus vermiculatus*) (Comstock and Ehleringer, 1992; Dealy et al., 1981) (Fig. 7).

Often in close proximity to one another, shadscale and greasewood communities are typically distributed along elevational gradients (Shreve, 1942). Greasewood communities tend to occupy the lowest elevations where soil salinity and the water table are highest (Blaisdell and Holmgren, 1984; Comstock and Ehleringer, 1992; Dealy et al., 1981). In contrast, shadscale communities generally prefer moderately saline soils that are well-drained, often in more upland environments (Comstock and Ehleringer, 1992). Many of the plants in these communities have evolved interesting adaptations to live in the harsh alkali surroundings,

Fig. 7 Salt desert scrub plant community in the Northern Great Basin. Sources: Photo by Greg Burke.

such as elevated internal salt concentrations to allow for water absorption in the highly saline environment (Taylor, 1992). Other common shrubs associated with salt desert scrub include fourwing saltbush (*Atriplex canescens*), winterfat (*Krascheninnikovia lanata*), spiny hopsage (*Atriplex spinosa*), mormon tea (*Ephedra viridis*), rabbitbrush (*Chrysothamnus* spp.), and big sagebrush (*Artemisia tridentata*) (Dealy et al., 1981; Franklin and Dyrness, 1988; Kagan et al., 1999).

Riparian Areas

Riparian areas are the least abundant habitat in the Northern Great Basin, constituting less than 1% of the region's land surface (Dobkin et al., 1998). However, of the described terrestrial wildlife species that are found here, up to 80% depend on these unique zones during their lifetime (Thomas et al., 1979a). The outsized importance of riparian areas to the region's wildlife centers on the relative abundance of water, diversity of vegetation, and the stark contrast they form to the surrounding arid shrub communities (Fig. 8).

In the Northern Great Basin, riparian areas includes both lentic—lakes, ponds, seeps, bogs and meadows—and lotic systems—rivers, streams and springs (Thomas et al., 1979a). They are some of the most productive plant communities and provide complex structure and species diversity critical to resident and migratory wildlife. The often linear shapes of riparian areas allow them to cut through elevational gradients, connecting seasonal wildlife habitats and serving as migratory corridors (Dealy et al., 1981). Dramatic differences between the arid shrub steppe and riparian plant communities create conditions where wildlife species with broad ecological requirements interact (known as the edge effect) and make them hotspots for biological diversity (Thomas et al., 1979b).

Tree Communities

On the upper reaches of the Northern Great Basin's mountain ranges, sagebrush and shrubs often give way to tree dominant or co-dominant communities, most notably curleaf mountain mahogany (*Cercocarpus ledifolius*), aspen (*Populus tremuloides*), and juniper (*Juniperus occidentalis*). On the perimeter foothills and mountain ranges, coniferous forests are well established and even occur in a handful of isolated patches throughout the region (Anderson et al., 1998). While frequently limited in acreage, tree communities provide contrasting vertical cover from the surrounding low statured sagebrush steppe, and as a group play an especially important role in providing thermal and hiding cover for wildlife, most prominent being native ungulates such as elk (*Cervus elaphus canadensis*) and mule deer (*Odocoileus hemionus*) (Dealy et al., 1981).

Fauna of the Northern Great Basin

Hundreds of terrestrial vertebrate species rely on the Northern Great Basin's diverse habitats during their life histories. The semi-arid climate of much of the region has resulted in a mixed composition of both grassland and desert species (West, 1999). Some of the

Fig. 8 Riparian area in the Northern Great Basin. Sources: Photo by Greg Burke.

most visible species belong to the mammal, bird, reptile and amphibian groups, and together compose a core of the region's wildlife identity. Species from each of these vertebrate groups can be found here throughout the year, occupying habitats from the lowland basins to the high alpine ridge tops, utilizing a host of adaptations to survive within the region's harshest fringes.

Mammals

The complex climatic and topographic history of the Northern Great Basin has contributed to a high regional diversity of extant mammal species (Badgley et al., 2014). Classifications of Great Basin mammals have documented as many as 172 native species (Rowe and Matocq, 2014) and can differ widely depending on how the Great Basin is defined. Riddle et al. (2014) described a core group of 94 extant mammal species distributed across the Great Basin shrub-steppe. Nearly all of them can be found in the Northern Great Basin, including some of North America's most recognizable fauna such as the pronghorn, coyote, and mountain lion.

One group of mammals disproportionately contributes to the region's high mammalian diversity. Of the 94 core species described by Riddle et al. (2014), 45 species are rodents. The high diversity of rodents is largely attributed to the ability of these small mammals to finely subdivide their habitat along elevational gradients (Badgley et al., 2014). Rodents are found in all of the major habitats in the region, serving as prey for numerous predator species and acting as important seed dispersers for native plants.

Perhaps the most recognizable mammal in the Northern Great Basin is the pronghorn (*Antilocapra americana*) (Fig. 9). The only extant member of the family Antilocapridae, the pronghorn is the fastest land animal in North America, able to reach speeds up to nearly 100 km per hour. Considered a sagebrush obligate species (Rowland et al., 2006), pronghorn are well adapted to the extreme temperatures and low shrub communities characteristic of much of the Northern Great Basin (O'Gara, 2004). Unlike other North American wild ungulates, pronghorn do not rely on tall vegetation for hiding cover, preferring rolling topographies with a mix of grass and shrub species (Yoakum, 2004). Having evolved the largest eye relative to their size of any North American ungulate, the pronghorn instead relies on both its eyesight and speed to evade predators (O'Gara, 2004).

The sagebrush steppe is also critical habitat for numerous other mammal species. Like the pronghorn, the sagebrush vole (*Lemmiscus curtatus*) and pygmy rabbit (*Brachylagus idahoensis*) are both considered sagebrush obligate species, relying on intact blocks of sagebrush to survive (Rowland et al., 2006). Several other species of conservation concern similarly rely on the sagebrush steppe, including the kit fox (*Vulpes macrotis*), white-tailed jackrabbit (*Lepus townsendii*), Ord's kangaroo mouse (*Dipodomys ordii*), and Merriam's shrew (*Sorex merriami*) (Rowland et al., 2006).

The Northern Great Basin's often discrete riparian communities are disproportionately important for the majority of the region's mammal species. Recognized as the most critical wildlife habitat in the high desert, riparian areas have the potential to provide mammal species with all three components of habitat—food, shelter, and water (Thomas et al., 1979a). Species such as the North

Fig. 9 Pronghorn (*Antilocapra americana*). Sources: Photo by Greg Burke.

American beaver (*Castor canadensis*), muskrat (*Ondatra zibethicus*), and the North American otter (*Lontra canadensis*) are completely dependent on riparian areas to survive (Thomas et al., 1979a).

At higher elevations, taller tree communities afford mule deer and elk the tall vegetation they require for security cover. Bighorn sheep (*Ovis canadensis*), while sometimes found in big sagebrush and tree communities, more often use the region's steep escarpments and cliff faces for cover and protection from predators (Van Dyke et al., 1983). Other species found in these communities include numerous bat species, bushy-tailed woodrat (*Neotoma cinerea*), and the mountain cottontail (*Sylvilagus nuttallii*).

Birds

Birds encompass the greatest variety of vertebrates in the Northern Great Basin. Approximately 390 bird species are known to have occurred in Northern Great Basin (Marshall et al., 2006). Of these, 200 species have been confirmed to breed there (Adamus et al., 2001), and as many as 96 species are sufficiently adapted to succeed as year-round residents (Marshall et al., 2006).

Sagebrush is the defining habitat of the Northern Great Basin. Thirty-seven bird species are extensively dependent on the sagebrush shrub steppe ecosystems in the region (Dobkin and Sauder, 2004). The sage thrasher (*Oreoscoptes montanus*), Brewer's sparrow (*Spizella breweri*), and sagebrush sparrow (*Artemisiospiza nevadensis*) are considered sagebrush obligates, and are completely dependent on sagebrush for breeding and brood-rearing (Patterson, 1952). However, only a single bird species, the greater sage-grouse (*Centrocercus urophasianus*), spends its entire life cycle in the sagebrush steppe habitat (i.e., as both a sagebrush obligate and endemic species) (Fig. 10). Furthermore, it is the only bird species that consumes sagebrush as a part of its diet (Girard, 1937; Griner, 1939; Batterson and Morse, 1948; Schroeder et al., 1999). The Northern Great Basin and its large expanses of intact sagebrush communities, is one of only a few remaining strongholds throughout the range of this magnificent bird.

The greater sage-grouse is a large bird, standing at approximately half a meter tall. This iconic species is legendary for its exotic mating ritual, where a group of up to 150 males gather in leks to attract females and attempt to mate. The display involves repeatedly inflating and popping two gular air sacs that can hold up to a gallon of air. The displays go on for hours in the early morning for up to 3 months during the spring. Female sage-grouse are highly selective in choosing a mate, and despite all the effort put on by multiple males, most mating is consummated by just one male (Patterson, 1952; Wiley, 1973).

Other habitats in the Northern Great Basin are equally important to supporting the region's bird communities. Lake Abert, a 15-mile long hypersaline body of water, supports vast quantities of brine shrimp and brine flies, providing a crucial stopover and feeding site along the Pacific Flyway. Under optimal conditions, up to 300,000 Wilson's phalaropes (*Phalaropus tricolor*), 20,000 eared grebes (*Podiceps nigricollis*) and 40,000 American avocets (*Recurvirostra americana*) will stop and gather at the lake in preparation for their southward migration in the fall. Similarly, snow (*Chen caerulescens*), Ross's (*Chen rossii*), and greater white-fronted (*Anser albifrons*) geese gather in the tens of thousands in the Harney Basin during their spring and fall migrations, utilizing critical networks of riparian plant communities.

On the high elevation slopes of fault block mountains such as the Steens, black rosy-finch (*Leucosticte atrata*) and golden eagle (*Aquila chrysaetos*) find refuge. Volcanic formations and rimrock cliffs provide nesting habitat for white-throated swift (*Aeronautes*

Fig. 10 A male Greater Sage-Grouse (*Centrocercus urophasianus*). Sources: Photo by Alan St. John.

saxatilis), Say's phoebe (*Sayornis saya*), prairie falcon (*Falco mexicanus*), rock wren (*Salpinctes obsoletus*), and canyon wren (*Catherpes mexicanus*) (Marshall et al., 2006). And in the region's woodland habitats, Townsend's solitaire (*Myadestes townsendi*), juniper titmouse (*Baeolophus ridgwayi*), and blue-gray gnatcatcher (*Poliophtila caerulea*) can be found (Littlefield, 1990).

Reptiles and Amphibians

While not as rich in species as the mammalian and avian communities, numerous amphibians and reptiles have evolved interesting adaptations to survive and prosper in the severe climate of the Northern Great Basin. As ectotherms, lizards and snakes do not need to constantly supply themselves with calories to produce metabolic heat, allowing them to survive on amazingly small amounts of nourishment in extremely arid environments. They are well represented in the Northern Great Basin. Amphibians, while limited in distribution and diversity due to the scarcity of water, are nevertheless represented by salamanders, frogs and toads. In total, 19 reptile species and 5 amphibian species occur in the region.

The relatively warmer salt desert scrub habitats of the Northern Great Basin contain higher concentrations of reptiles than the surrounding mountain ranges and sagebrush steppe. Typical of these communities is the long-nosed leopard lizard (*Gambelia wislizenii*), which can grow to 30 cm in length, and the equally large in size western whiptail (*Aspidoscelis tigris*). Characteristic of some species in extremely arid regions, the leopard lizard does not require water to survive and instead can obtain its moisture from food sources. This adaptation allows them to thrive in the lowland basins where rainfall can be as little as 12 cm a year. Also inhabiting salt desert scrub communities is the desert horned lizard (*Phrynosoma platyrhinos*), having evolved a spine-clad body and head to ward off coyotes and predatory snakes such as the striped whipsnake (*Masticophis taeniatus*) and racer (*Coluber constrictor*).

On adjacent lower foothills, often in the transition zones between the salt desert scrub and sagebrush steppe shrub lands, the diminutive side-blotched lizard (*Uta stansburiana*) and somewhat larger western fence lizard (*Sceloporus occidentalis*) can be found. Preying upon these two species is the larger Great Basin collared lizard (*Crotaphytus bicinctores*). This predatory reptile can attain a total length of 33 cm, and when startled, often runs on its hind legs much like bipedal dinosaurs once did.

In riparian environments, the distinct chorus of Pacific treefrogs (*Pseudacris regilla*) can often be heard. This small, ubiquitous species is polymorphic, featuring individuals within the same population that are green, tan, brown, gray, or rarely, blue. Other amphibians found in the lush vegetation of riparian communities include the larger Columbia spotted frog (*Rana luteiventris*), western toad (*Anaxyrus boreas*), and the long-toed salamanders (*Ambystoma macrodactylum*). Reptilian predators include the common garter snake (*Thamnophis sirtalis*) and western terrestrial garter snake (*Thamnophis elegans*).

Across nearly all habitats in the Northern Great Basin, several snake species are predominantly nocturnally active. During the peak daytime heat in the summer months, many reptiles stay hidden in cool subterranean retreats. As the sun sets and temperatures moderate, a host of species become active. Gopher Snakes (*Pituophis catenifer*) are usually the first to be out, along with Great Basin Rattlesnakes (*Crotalus oreganus lutosus*). Later, the Desert Night Snake (*Hypsiglena chlorophaea*) utilizes its cats-eye vertical pupils to seek out small lizards asleep in crevices. To subdue its prey, the Desert Night Snake utilizes a mild saliva venom that flows down grooves in the snake's enlarged rear teeth.

During summer precipitation events, a unique arid-adapted amphibian of the salt desert scrub and sagebrush steppe emerges. This is the Great Basin spadefoot (*Spea intermontana*), a small toad with a sharp-edged protrusion on the heel of each rear foot (Fig. 11). These nodules, or spades, are utilized to rapidly dig backwards into soil where the toad waits out surface dry spells, which can extend for over a year during prolonged droughts (Hovingh et al., 1985). In early springtime, male spadefoots attract females with their loud monotone chorus, breeding in temporary rain-pools and any other available shallow water. Well adapted to the

Fig. 11 Great Basin spadefoot (*Spea intermontana*). Sources: Photo by Alan St. John.

region's aridity, the resulting gelatinous egg clusters hatch in 2 or 3 days; and before the aquatic habitat evaporates, the tadpole larvae can transform into terrestrial adults within 2 weeks.

Ascending the Northern Great Basin's fault-block ranges, such as Hart Mountain and Steens Mountain, the surroundings change rapidly. The salt scrub of alkali flats gives way to slopes and level ridge-tops of sagebrush, bunchgrasses, juniper woodlands, and patches of mountain mahogany. Here can be found species such as the sagebrush lizard (*Sceloporus graciosus*), western skink (*Plestiodon skiltonianus*), and rubber boa (*Charina bottae*)—the most northerly-ranging true boa in the world (St. John, 2002).

Possibly the most iconic sagebrush steppe reptile in the Northern Great Basin is the endemic pygmy short-horned lizard (*Phrynosoma douglasii*) (Fig. 12). Sometimes wrongly called a horned toad, this lizard rarely grows to more than seven centimeters in total length. Recent field studies have disclosed that short-horned lizards routinely hibernate by burying in sand just ten to twelve centimeters below the surface, freezing solid for months at a time (Mathies and Martin, 2008). When the warmth of springtime arrives, the lizards thaw unharmed. Remarkable for an ectothermic reptile at the Northern Great Basin's latitude, the pygmy short-horned lizard has been recorded at nearly 2400 m elevation (Lahti et al., 2007), surviving in the stunted sagebrush and bunchgrass habitats of the region's mountain summits. In these rarefied zones that are snowbound for months on end, short-horned lizards spend the majority of the year in hibernation.

Threats to Biodiversity

The Northern Great Basin of today remains a stronghold of the sagebrush steppe and high desert ecosystems. However, the natural systems here and elsewhere in the Great Basin are among the most threatened in all of North America (Heinz III, 2002; Chambers

Fig. 12 Pygmy short-horned lizard (*Phrynosoma douglasii*). Sources: Photo by Alan St. John.

and Wisdom, 2009; Wisdom et al., 2005). Nearly two centuries of human caused impacts have resulted in landscape-scale fragmentation and degradation of some of the continent's most widespread ecosystems. Protecting relic landscapes from anthropogenic stressors is paramount to providing the greatest chance of maintaining the health of these systems.

More than 30 million hectares of the sagebrush steppe have been degraded, a staggering half of its historic range. Agriculture, livestock grazing, housing development, energy development, altered fire regimes, and a host of alterations to riparian systems, among other changes, have impacted native communities across the Great Basin and arid west. Threats posed by the proliferation of non-native plant species, specifically cheatgrass (*Bromus tectorum*), and the expansion of juniper into higher elevation shrub communities, are resulting in landscape scale impacts. Climate change, predicted to have the greatest impact on arid systems such as those of the Great Basin, is already being realized on the landscape (Chambers and Wisdom, 2009). Decreases in winter snowpack in the Great Basin are some of the greatest observed in the United States and are expected to continue, reducing spring runoff and water availability throughout the year (Chambers and Wisdom, 2009; Mote et al., 2005).

These changes are having far reaching negative consequences for the flora and fauna of the Great Basin and arid west. Over 350 plants and animals within the historic range of the sagebrush steppe have been identified as species of concern (Wisdom et al., 2005). Shrub communities, and their herbaceous understories, are being heavily impacted by cheatgrass leading to changes in hydrology, fire regimes and connectivity of wildlife habitat. In many place, riparian areas are no longer functioning properly, decreasing the availability of critical water sources for all life. The ripple effect of these impacts extend far beyond the arid west, creating barriers for migratory species and additional pinch points for birds moving along the chain of habitats known as the Pacific Flyway.

The multitude and complexity of these threats pose significant challenges to maintaining ecological processes and regional biodiversity, demanding creative solutions, robust partnerships and adequate resources to effectively combat them. Roughly two thirds of the Great Basin is public land, managed by the federal government of the United States. In the face of losing native plants, watershed function and native wildlife species, places with high biodiversity and healthy native communities should be prioritized for conservation management and protection through administrative and legislative actions. Safeguarding systems like those of the Northern Great Basin, with high levels of endemism and native species, will help maintain the unique biodiversity of the high desert biome in the face of an uncertain future.

Abstract

The Mongolian Gobi Desert supports globally-significant biodiversity, and is part of the largest steppe ecosystem in the world that supports its historic wildlife assemblage, including long distance wildlife migrations, as well as traditional nomadic pastoralism. Like other development frontiers in arid lands, the wildlife and biodiversity of the region are threatened by the rapid growth of mining and related infrastructure. Globally, environmental licensing and mitigation face challenges in practice. Mitigation is typically a reactive process conducted on a site by site basis that does not account for the landscape context, or the cumulative impacts of multiple projects and regional biogeography. The Mongolian government has developed a national mitigation framework based on systematic conservation planning adapted to guide landscape-level mitigation. The framework balances development and conservation goals to designate new protected areas and guide offset design, and demonstrates that landscape-level mitigation based on stakeholder- and data-driven conservation planning is possible and practical.

Introduction

The Gobi Desert basin lies across southern Mongolia and northwestern China between the Mongolian Altai and Khangai mountains and the Himalayan Plateau (see map in [Fig. 1](#)). This region is a cold desert with a continental climate and long, cold winters. Average temperatures range from below -20°C in January to over 33°C in July ([Hijmans et al., 2005](#)). In the rain shadow of the Himalayas, precipitation ranges from less than 40 mm in extreme arid areas to over 200 mm in the Gobi-Altai mountains ([Hijmans et al., 2005](#)), and varies greatly interannually, with some areas not receiving any measurable precipitation for years at a time ([Vandendorj et al., 2015](#)).

The name “Gobi” comes from the Mongolia word “Govi” for a dry landscape with characteristic arid vegetation including palatable forage species (*Allium* and *Nitraria* spp.) and rare medicinal plants. Gobi desert vegetation is a mix of true desert, desert grasslands, and steppe. Despite the climate, the Mongolian portion of the Gobi Desert region supports globally-significant wild lands and wildlife, and is part of the largest steppe ecosystem in the world that supports its historic wildlife assemblage, including long distance wildlife migrations ([Batsaikhan et al., 2014](#)). Historically, this region was near the center of the Mongol Empire (c. 1206–1294) and has been crossed by human migrations and trade routes for 5000 years ([Hare, 2009](#)).

Arid lands, which include the semi-arid grasslands and deserts of the Gobi Desert region, cover a third of the world’s land mass ([Mortimore et al., 2009](#)) and support unique biodiversity and many endangered species ([Durant et al., 2012](#); [IUCN, 2011](#)). However, as much as 20% has experienced degradation ([Reynolds et al., 2007](#); [Safriel, 2006](#); [UNCCD, 1994](#)) and less than 10% of arid lands benefit from some form of protection ([Hoekstra et al., 2005](#)). Arid and semi-arid biomes are home to 20% of the world’s population, mostly subsistence farmers and pastoralists ([Mortimore et al., 2009](#)). The dry climate promotes the formation and concentration of important minerals and salts through the movement and evaporation of water. Half of the world’s copper and uranium and 75% of world oil reserves are in arid lands ([UNEP, 2006](#)).

Parts of the Mongolian Gobi Desert region have been identified as among the world’s largest and most intact (least converted) remaining wild areas ([Allan et al., 2017](#); [Kennedy et al., 2019](#)), and the human population density was very low historically and still is today ([ECJRC and CIESIN, 2015](#)). The Mongolian Gobi Desert currently supports more than 30 mammals, herptiles, and birds listed as nationally threatened or endangered ([Clark et al., 2006](#); [Terbish et al., 2006](#); [Gombobataar et al., 2011](#)), including the world’s largest remaining populations of Asiatic wild ass or khulan (*Equus hemionus*), wild Bactrian camel (*Camelus ferus*), Gobi brown bear (*Ursus arctos gobiensis*), Siberian ibex (*Capra sibirica*), Goitered gazelle (*Gazella subgutturosa*), and Mongolian gazelle

Fig. 1 Gobi Desert region as delineated by WWF (Olson et al. 2001) and Dash (2007). Basemap: ESRI (2019).

(*Procapra gutturosa*), (Kaczensky et al., 2015; Mallon, 2008a,b). The low mountain ranges also support one of the most stable and productive populations of Snow Leopards (*Panthera uncia*) in the global range (Sharma et al., 2014; Jackson et al., 2009).

The Mongolia steppes and desert grasslands also support traditional nomadic pastoralism that originated thousands of years ago. Mongolia nomadic pastoralists spend the winter at fixed households and shelters, and spend spring, summer, and autumn traveling between seasonal camps and pastures, though grazing practices and herd composition vary by geography and climate. In less productive desert grasslands, pastoralists typically visit as many as 10–15 seasonal pastures over the course of a year. In Mongolia, domestic livestock include horses, camels, yak, and cattle, though sheep and goats are the most numerous. Extreme winter weather events, sometimes coupled with summer drought, can cause catastrophic die-offs of livestock and wildlife. These weather events occur frequently enough to earn the name “dzud.” Dzud events take a variety of forms, including “white dzud”—deep snow reducing access to pasture forage, “black dzud”—extreme cold and no snow reducing forage and water availability, “storm dzud”—high winds and heavy snow, “iron dzud”—impenetrable ice covering pasture forage, “combined dzud”—deep snow and extreme cold, and “hoofed dzud”—out of season movements of many livestock to one pasture that eliminates forage with trampling and grazing (Begzsuren et al., 2004; Fernandez-Gimenez et al., 2011).

Though the Mongolian Gobi Steppe system still supports its historic wildlife and pastoral traditions, the wildlife and pastoral livelihoods face increasing threats and pressures following the transition from a soviet to market economy in 1990. Pastoral systems and grazing practices have changed in response (Fernandez-Gimenez and Batbuyan, 2004; Fernandez-Gimenez, 2001), and the number of livestock has nearly tripled, growing from 25 to over 66 million animals, in fewer, larger herds (National Statistical Office of Mongolia, 2018). This has resulted in overgrazing, particularly in areas near rural population centers and water sources (Stumpp et al., 2005), though estimates of the degree and extent of rangeland degradation vary (Jamsranjav et al., 2018; Addison et al., 2012).

These rapid changes have led to concerns about ecological tipping points, the loss of knowledge of traditional herding practices, and the loss of cultural identity (Fernandez-Gimenez et al., 2017).

A possibly more urgent threat to wildlife and biodiversity is the cumulative impacts of rapid growth of mining and related infrastructure (Suzuki, 2013; Batsaikhan et al., 2014). Mongolia is rich in mineral resources, and mineral exploration and extraction is increasing dramatically. In 2012, 14% of Mongolia's surface area and 24% of the Gobi study area was leased for mineral extraction or exploration (MMRE, 2012). Though the direct impacts of mining on land and water are significant and can reach far beyond the mine site, perhaps the most urgent threat to wildlife is created by transportation infrastructure and traffic to support mining operations that create barriers to movement (Nandintsetseg et al., 2019; Batsaikhan et al., 2014; Ito et al., 2013).

Development Frontiers and the Challenge of Mitigation

The trend of development in Mongolia is similar to other development frontiers around the world. Growing resource demands are pushing development to new frontiers in developing countries that support important biological diversity and have not seen this level or pace of infrastructure development. Impacts associated with development are the most significant anthropogenic drivers of biodiversity decline (Newbold et al., 2015), and an estimated 20% of the world's remaining natural lands are at risk of fragmentation from mining, energy, agriculture, and urban expansion (Oakleaf et al., 2015). Existing mechanisms for managing impacts and losses—environmental licensing, mitigation requirements, and conservation planning—fall short in practice, in part because development and conservation planning are typically independent, isolated processes (Kiesecker and Naugle, 2017).

Environmental licensing mechanisms such as Environmental Impact Assessment (EIA) and the mitigation hierarchy play a critical role in controlling the environmental impacts of development projects (McKenney and Kiesecker, 2010; Saenz et al., 2013). EIA laws require developers to assess impacts and submit mitigation plans to obtain a permit before construction and operation can begin, and EIA has been legally adopted in almost all countries in the world (Morgan, 2012). EIAs proactively examine the environmental impacts of planned developments, typically individual projects, with the goal of preventing or mitigating environmental damage through the application of the mitigation hierarchy: first avoid impacts, then minimize, then restore, and last compensate for residual impacts through offsets (McKenney and Kiesecker, 2010; BBOP, 2012; Ekstrom et al., 2015). To avoid impacts to rare or vulnerable biodiversity, measures are taken at the beginning, such as careful placement or timing of infrastructure construction and operation. For impacts that cannot be avoided, minimization measures are designed to reduce the duration, intensity, and/or extent. Restoration measures seek to rehabilitate degraded ecosystems after impacts. Finally, to compensate for remaining, residual impacts, biodiversity offsets are management interventions outside the impact area, such as protecting other areas where biodiversity loss is projected or restoration of similar, degraded habitat offsite (Kiesecker et al., 2009). Offsets have great potential as a source of funding to underwrite the costs of effective protection and management, given the appropriate sequence—avoid, minimize, and then offset—is followed.

However, effective mitigation faces challenges in practice. Mitigation efforts often skip the first, critical step in the mitigation hierarchy, avoidance (Clare et al., 2011; Villarroya et al., 2014; Phalan et al., 2018). EIAs are typically conducted on a project-by-project basis that does not consider the landscape context, or regional biogeography and cumulative impacts of multiple projects. Though consideration of the landscape context of impacts is a fundamental principle of effective mitigation (BBOP, 2012; Gardner et al., 2013; Pilgrim and Bennun, 2014; Ekstrom et al., 2015), little guidance exists for how to determine when and where impacts should be avoided or proceed (Kiesecker et al., 2010; McKenzie and Kiesecker, 2010). Offset design must also consider the landscape context to ensure ecological equivalence of the impact and offset, and to achieve “additionality,” (i.e., maximize conservation benefit by aligning with broader regional priorities and goals. Offset design must also account for the security or permanence of offset investments by considering risks and conflicts with future development).

Planning for Conservation and Mitigation in Mongolia

Mongolia established perhaps the world's longest continuously protected nature reserve, Bogd Khan, in 1778. Following transition from a Soviet economy to market economy, and in anticipation of mining boom, the government set an ambitious goal of protecting 30% of all natural habitats with a Master Plan for Protected Areas (Parliament of Mongolia, 1998, 2014) and published a Biodiversity Conservation Action Plan (MNE, 1996) that recommended designing a reserve network of strictly protected areas, national parks, and heritage areas. As of 2008, Mongolia had designated 74 national protected areas covering about 217,000 sq. km. or 14% of the country (MNET, 2008). The Nature Conservancy (TNC) established a Mongolia country program office in 2008 and has been working to apply the Development by Design strategy (Kiesecker et al., 2010) to balance development and conservation goals, with focus on landscape-level conservation planning to guide mitigation decisions, specifically regarding avoidance and offsets, and policy guidance to strengthen licensing and mitigation.

In 2013, following a pilot study in the Eastern Grasslands, TNC produced a landscape level conservation plan for the Mongolian Gobi region in collaboration with national and provincial governments, universities, and NGOs. This plan identified a set of priority conservation areas, referred to as a “portfolio,” that could maintain the biodiversity and ecological processes representative of the region given adequate protection and management as high quality core habitat within a larger landscape matrix that supports habitat use and movement. The portfolio was designed to (a) include national protected areas, (b) meet representation goals for the

amount and distribution of focal biodiversity elements—terrestrial ecosystems and threatened species—based on the government commitment to protect 30% of all natural habitats, and (c) optimize for ecological condition based on a spatial index of disturbance and cumulative anthropogenic impacts. Portfolio sites were delineated through site selection analysis with MARXAN spatial planning software (Ball et al., 2009). Spatial datasets were chosen and developed to address the scope and scale of conservation planning across the large, data-scarce Mongolian Gobi landscape (Heiner et al., 2013), and methods follow systematic conservation planning approaches (Margules and Pressey, 2000; Groves et al., 2002; Groves, 2003) adapted for landscape level mitigation (Kiesecker et al., 2010).

Portfolio design also considered conflict with planned mining. Where proposed portfolio sites and mineral exploration leases intersected, these conflict areas were reevaluated. Conflict areas with rare or vulnerable habitat, as defined by several criteria, were designated as areas of critical conservation significance where mining should be avoided. The other, remaining conflict areas were removed from the proposed portfolio and replaced with sites of similar ecosystem composition outside exploration leases. In this way, the portfolio design balanced tradeoffs between conservation and development goals based on the regional distributions of biodiversity values and development potential. The final portfolio consisted of 50 sites, covering 195,000 sq. km. or 37% of the Mongolian Gobi Desert study area, and contained at least 30% of the area distribution of all the focal ecosystem types.

New Protection and Avoidance Outcomes

After completion of the Gobi Desert conservation plan, 68,800sq. km. of new protected areas were designated based on the portfolio. With the establishment of these new protected areas, 160 exploration and application leases have been retired. The planning process was formally approved by the Mongolian Academy of Sciences in 2014 (MAS, 2014), establishing it as the basis for landscape level conservation planning and the national framework for implementing both the government protected area commitment and the mitigation hierarchy, specifically to determine areas to avoid development. Current legislation prohibits mining in national and local protected areas, and therefore protected area designation functions as a mechanism to implement avoidance (Mongolian Law on Mining, Parliament of Mongolia, 2016). Thus, the portfolio plays two roles: prioritizing new protected areas and implementing the mitigation hierarchy. The Mongolian Gobi Desert planning process was expanded to cover Mongolia and completed in 2017 to produce a national mitigation framework based on the conservation area portfolio and supporting datasets. Nationally, ~177,000 sq. km. of new protected areas have been established based on the national conservation portfolio and planning process.

Offset Outcomes

Offsets are a mechanism to ensure that environmental impacts of development are balanced by environmental gains with the overall aim of achieving a net neutral or positive outcome. Biodiversity offset design must overcome several methodological obstacles including how to ensure ecological equivalence to losses in terms of the ecological systems and/or species impacted, where to locate offsets relative to impacts, and how to minimize uncertainty and conflicts with future development (Kiesecker et al., 2009; Bull et al., 2013; Sochi and Kiesecker, 2016). The conservation portfolio and the supporting spatial datasets provide a mechanism to address these challenges by directing offsets to portfolio sites that can become protected areas. Designating these sites as protected areas maximizes biodiversity conservation benefits and long-term security, and also provides a mechanism to direct offset funds to restoration and management.

In 2012, the Mongolian Parliament amended the EIA law to require biodiversity offsets for all new development projects (Parliament of Mongolia, 2012). The law requires developers to calculate a minimum offset cost following specifications published by the Ministry of Environment, Green Development, and Tourism (MEGDT) that are based on the conservation portfolio and supporting datasets (MEGDT, 2014). The specifications define a method for calculating compensation according to impacts measured in terms of area, magnitude, duration, and four landscape conservation factors based on ecosystem composition, ecological condition, critical habitat designation, and proximity to portfolio sites. The four landscape conservation factors are designed to require higher compensation for impacts to rare and highly productive ecosystems, areas in good ecological condition, and/or near the portfolio sites, with the goal of steering development away from these areas. To support transparent and replicable implementation of this regulation, the MEGDT developed a Mitigation Design GIS Toolset to apply these specifications and made the conservation planning datasets publicly available through a web-based GIS application and a public GIS archive (TNC, 2016).

Additional Applications of Landscape Planning Framework

The datasets developed to support this framework have also been instrumental for implementing protection of riverine wetlands. At least 40% of the area of riverine wetlands in Mongolia may be degraded by heavy summer livestock use (Jamsranjav et al., 2018) and rivers are further threatened by wetland conversion and water withdrawals by mine operations. In 2009, Mongolia passed a law protecting water resources that prohibits mining near water sources (Parliament of Mongolia, 2009) but does not specify how to delineate these protection zones, and available maps and surveys are inconsistent. The terrestrial ecosystem classification developed

for the conservation plans includes a delineation of floodplains and riverine wetlands that has been the basis for formal protection and effective local implementation of the law in seven major river basins (WWF Mongolia, 2015).

Additional Challenges

Linear Infrastructure: Transportation infrastructure and traffic supporting mining operations create barriers to wildlife movement that are an urgent threat to the viability of wide ranging species including Mongolia's iconic plains ungulates (Ito et al., 2013; Batsaikhan et al., 2014; Wingard et al., 2014; Olson and van der Ree, 2015). Protected areas alone cannot effectively conserve the current populations of wide ranging species (Runge et al., 2014). Mitigation of impacts to movement and connectivity of wide ranging species is a difficult and urgent challenge, requiring improvements in both policy guidance and practical mitigation measures that include siting analysis, wildlife passage structures, and traffic curfews, all of which require more research as well as local studies to guide implementation. Mitigation measures for transportation are summarized by van der Ree et al. (2015). Climate change will likely require further shifts in ranges and habitat use and compound the threat of habitat loss, fragmentation, and movement barriers (Singh and Milner-Gulland, 2011).

Ground Water Management: In the Gobi Desert, water withdrawals to support mining operations could reduce groundwater supplies, affecting wells, springs, and vegetation productivity, and ultimately reducing water and forage for livestock and wildlife. In the Inner Mongolian grasslands of China, water withdrawal for coal mining has been identified as the dominant cause of loss of surface water (Tao et al., 2015). Because current understanding of the hydrology of this system is limited, it is difficult to estimate the amount, spatial extent or duration of mining-related ground water impacts.

Climate Change: Mongolia and Central Asia have been warming since the 1950s, at a faster rate than before over the last 1000 years (Chen et al., 2009; Davi et al., 2015), and producing hotter, more frequent droughts (Pederson et al., 2014; Batima et al., 2005). This trend is predicted to continue and cause declines in soil moisture and rangeland productivity (Angerer et al., 2008). Surface- and ground-water sources and stream flows have declined recently across Mongolia (MNET, 2009; Fassnacht et al., 2011). These changes to rangelands and water sources will have serious implications for wildlife, pastoralists, and economic development.

Conclusion

Mitigation frameworks and conservation planning are supported by large bodies of research and guiding principles, but both fall short in practice. Historically, mitigation has been a reactive process occurring at small spatial scales on a site-by-site basis and little guidance exists for regulatory authorities to decide when and where to avoid, minimize, or offset. Most landscape-level conservation plans do not produce tangible conservation actions (Prendergast et al., 1999; Knight et al., 2008). A root cause of these gaps in practice is that development and conservation planning are typically independent, isolated processes (Kiesecker and Naugle, 2017).

Like many other arid lands, the Mongolia Gobi Desert is a data-scarce landscape with globally significant biodiversity facing rapid development. Mongolia's national mitigation framework is designed to guide site level mitigation decisions with a landscape-scale information system, and move from a reactive, site by site approach to a proactive, regional vision that balances goals for development and conservation. This demonstrates that landscape-level mitigation based on stakeholder-driven and data-driven conservation planning is both possible and practical, and can provide a mechanism to fund conservation in proportion to development.

Abstract

Little is known about ecological interactions between large carnivores in arid landscapes. A review of the densities, diets and foraging ecology, as well as the relations between the large carnivores in the arid Kalahari, illustrates the way they have successfully adapted to arid conditions, and highlights some of the differences in these relationships with those in more mesic areas. Relative densities of the large carnivores are more even, community structure is different, with the inclusion of the brown hyena and the disappearance of the African wild dog. Resource partitioning is more acute and diet flexibility is shown. The relative contribution to animals killed by predation is more equitably shared by the predator community, and high rates of food loss by smaller carnivores to larger ones has not been recorded. More attention should be given to research and conservation of these species in arid areas.

Introduction

Adaptation is the evolutionary process whereby an organism is able to survive in a habitat. Because of the variety of habitats, and the ever-changing nature of ecosystems, organisms are forced to adapt to changes in order to survive through the process of natural selection. Most large African carnivores are widely distributed and able to adapt to different savannah regions, but they tend to disappear in more extreme habitats such as rain forests and deserts. The leopard (*Panthera pardus*) is the most widely distributed and adaptable large carnivore species, able to survive in almost all terrestrial habitats. The brown hyena (*Hyaena brunnea*) and its northern relative the striped hyena (*Hyaena hyaena*) are primarily found in arid regions.

Most studies of large African carnivores have taken place in areas that receive an average of 450 mm or more rainfall per annum. However, a substantial part of Africa (43%) covers more arid areas, where annual rainfall is below 350 mm, and where the biomass of herbivores is lower. This would be expected to have an impact on large carnivore impacts and relationships. For example, lower large carnivore densities would be likely because of the decrease in food biomass and availability, and this might affect the larger or more specialized species more than generalists. Dietary habits and resource partitioning might change and prey species not often utilized in more productive areas might become more important. Foraging behavior too could be different. The carnivores might have to move further to find food. Finally, behavioral interactions between the carnivores might vary and the impact they have on each other take on a different dynamic.

Globally dry land areas have been neglected by both scientists and conservationists, because of their relatively low productivity (Durant et al., 2012). Yet they are home to species that are adapted to harsh and highly variable environments. One arid area that has received more attention than most, particularly with regards to the large mammalian carnivore community, is the arid Kalahari, specifically the southern part of the Kgalagadi Transfrontier Park (KTP).

In this article I review ecological and behavioral adaptations of large carnivores to the southern arid Kalahari. I consider relative densities, aspects of their diet, feeding ecology and behavior, as well as interactions between the species; I show that some of the generally accepted principles of African large carnivore community dynamics are not applicable to arid regions.

The Arid Kalahari

The Kalahari is a large, sand filled basin stretching from 24°S to 1°N in the west of Africa. The arid Kalahari is in the extreme south of the region. The KTP (24°S and 27°S and 20°E and 22°E) covering 36,000 km² in South Africa and Botswana is situated here and is a well conserved ecosystem. In this region the sand is piled into vegetated linear or seif dunes fixed by vegetation (Fig. 1). Two riverbeds, the Nossob and the Auob, which only flow for short periods and distances during abnormally wet years run through the KTP.

Fig. 1 Leopard on Kalahari dune.

There is no naturally occurring permanent water, but boreholes have been introduced especially along the riverbeds, but also sporadically in the dunes and on some pans. However, the natural fauna of this area, including the large carnivores, are adapted to survive without surface water.

Average annual rainfall in the southern KTP ranges from 150 mm in the south-west to 250 mm in the north. The vegetation type is classified as Kalahari Duneveld and is predominantly shrubby grassland, except along the riverbeds and some adjacent areas where an open *Acacia erioloba* and *Acacia haematoxylon* tree savannah is found (Fig. 2). Ecological conditions dictate that herbivorous animals are generally thinly distributed and need to be mobile. Gemsbok (*Oryx gazella*), blue wildebeest (*Connochaetes taurinus*) (along the riverbeds), steenbok (*Raphicerus campestris*), common duiker (*Sylvicapra grimmia*) and common ostrich (*Struthio camelus*) are sedentary species, whereas springbok (*Antidorcas marsupialis*), red hartebeest (*Alcelaphus buselaphus*), common eland (*Tragelaphus oryx*) and wildebeest (away from the riverbeds) are nomadic. These herbivores tend to concentrate along the riverbeds during the wet season and disperse in the dry season. Smaller herbivorous mammals such as Cape porcupine (*Hystrix africae australis*), hares (*Lepus* sp.) and springhares (*Pedetes capensis*) are widespread. Besides the large carnivores, mesocarnivores, such as black-backed jackal (*Canis mesomelas*), bat-eared fox (*Otocyon megalotis*), caracal (*Caracal caracal*) and African wild cat (*Felis silvestris*) are well represented (Mills and Mills, 2013).

Methods

The sand and sparse vegetation in the arid Kalahari provide unique conditions for tracking spoor over long distances with experienced Bushmen trackers. The sparse vegetation and open landscape also make it possible to visually follow habituated animals in

Fig. 2 Lions moving along the Auob riverbed.

a vehicle for long periods. These methods have been utilized by a number of researchers and have made it possible to compile accurate profiles of the diets of the large carnivores as well as revealing much about other ecological and behavioral adaptations of their life histories. The information used in this review for brown hyenas and spotted hyenas (*Crocuta crocuta*) are from Mills (1990), for cheetahs (*Acinonyx jubatus*) from Mills and Mills (2017), for lions (*Panthera leo*) from Eloff (1973, 1984) and for leopards from Bothma and le Riche (1984, 1986, 1990) and Bothma et al. (1997).

Results

Large Carnivore Densities

Unlike in moister African savannas where spotted hyena and lion tend to numerically and behaviorally dominate the large carnivore community, the relative densities of large carnivores in the arid Kalahari are generally lower but more even (Table 1). In fact the large carnivore that exists at the highest density, the brown hyena, is absent from the moister savannas. The wild dog (*Lycaon pictus*) is only sporadically seen in the KTP, and although it has been observed to occasionally breed successfully there, it is not known to have done so for the last 20 years (Mills and Mills, 2013). It is not dealt with here.

Diet and Prey Selection

Table 2 summarizes the diets of the five species in the arid Kalahari showing those species that make up 5% or more of their food. The two hyena species differ markedly in diet. The brown hyena has the widest diet of all the large carnivores, supplementing carrion of almost any origin, which makes up 69% of the diet, with wild fruits which make up 23% of the diet, especially the tsamma melon *Citrullus lanatus* and gemsbok cucumber *Acanthosicyos naudianus*. To a lesser extent it also eats reptiles, insects and birds eggs, especially ostrich eggs. Many feeding events involve picking up small items such as kill remains and wild fruits, consequently the species foragers solitarily although it breeds cooperatively. Hunting is almost irrelevant and contributes only about 2% of the biomass of its food. Although an accomplished and opportunistic scavenger, the spotted hyena is predominantly a hunter of gemsbok calves (Fig. 3) and wildebeest of all ages; kills contributing 65% of the biomass eaten. It tends to be the most specialized hunter in the arid Kalahari, with only two species making up 68% of kills.

The lion has a similar diet to the spotted hyena, although the two species tend to prey on different segments of the gemsbok population; adults in the case of lions, and calves in the case of spotted hyenas. This may be an example of resource partitioning as lions are better equipped to capture adult gemsbok than are spotted hyenas and so are able to dominate this food source.

The outstanding feature of the lion's diet is the preponderance of porcupines *Hystrix africaeaustralis* killed (Fig. 4), far more than has been recorded anywhere else (Hayward and Kerley, 2005). This is testimony to the low density of large herbivores in this arid

region and to the adaptability of the lion. The leopard also capitalizes on porcupines far more often in the arid Kalahari than anywhere else so far studied (Hayward et al., 2006a). However, in line with the leopard's reputation for killing carnivores, especially in less productive areas, small carnivores comprised 24% of its kills. These were the abundant and wide spread canids; black-backed jackal and bat-eared fox, which are killed in equal proportions, and the small-spotted genet *Genetta genetta*. Additionally, more typical antelope species were often utilized.

The cheetah's most important prey is the widespread steenbok, which does not feature in the leopard's diet to anything like the same extent. Other important prey for the cheetah are hares, springbok and springhare, and, for coalition males, gemsbok calves (Fig. 5) and adult ostrich. Most of these species are also not usually associated as important prey for cheetahs in other areas.

Whereas cheetah and leopard diets are similar in more mesic savannahs, only one species, steenbok, is represented in over 5% of their kills in the arid Kalahari. However, the steenbok is utilized four times more frequently by the cheetah than the leopard. The cheetah is well adapted to arid regions. Its ability to survive on small, cryptic and solitary species such as steenbok, hare and springhare is noteworthy and somewhat at odds to the conclusion of Hayward et al. (2006b) that it prefers to kill prey within a body mass range of 23–56 kg.

Although, the porcupine is less common in the arid Kalahari than other potential prey species of similar size such as steenbok, duiker, black-backed jackal and bat-eared fox (Mills 1990), it is less agile, albeit equipped with formidable defense structures through its quills. It is therefore easier for the more robust cats like lions and leopard to catch (the spotted hyena has also been observed killing it occasionally). The cheetah's small jaws and teeth, adaptations for speed, preclude its ability to kill a porcupine. The ubiquitous steenbok, on the other hand, is most vulnerable to the swift cheetah (Fig. 6), but less so to the other hunters. The reason for springbok being a less important prey than might be expected is because of their limited distribution, being almost exclusively confined to the river-beds.

Foraging Behavior

Table 3 summarizes aspects of the foraging behavior of the five species where known. Cheetahs were active for much less time than both hyena species, and while the hyenas are strongly nocturnal, the cheetah is mainly diurnal, although in the Kalahari more

Fig. 5 Cheetah males killing a gemsbok calf.

Fig. 6 Cheetah hunting steenbok.

Table 3 Aspects of foraging ecology and behavior of large carnivores from the southern Kgalagadi Transfrontier Park

	<i>Lion</i>	<i>Leopard</i>	<i>Cheetah</i>	<i>Spotted hyena</i>	<i>Brown hyena</i>

Mean distance (km) moved/24 h	11.8	13.9	11.0	27.1	31.1
Mean distance moved (km) between meals	25.2	24.5	15.9	32.7	9.2
Mean amount of food available at each meal (kg)	58	22	15	59	1.7
% Chases successful	39 ($n = 148$)	18 ($n = 110$)	43 ($n = 730$)	35 ($n = 136$)	9 ($n = 70$)

Data from Mills, M. G. L. 2015. Living near the edge: A review of the ecological relationships between large carnivores in the arid Kalahari. *African Journal of Wildlife Research* 45, 127–137.

nocturnal than is often taken to be the case. There are no data on activity for lions and leopards from the arid Kalahari, because these studies relied solely on tracking spoor. However, they are predominantly nocturnal.

Because they are active for longer periods than the cheetah, and probably the other cats as well, hyenas are generally more mobile and cover longer distances over a 24 h period than cats. For the brown hyena this is an important adaptation for a scavenging strategy, where food items are often widely scattered and quite small, as they usually comprise remains only. Mobility for the spotted hyena is important because, not only does it scavenge about one third of its food, it is also the most selective hunter of the large carnivores in the arid Kalahari. Additionally, it has the challenge of having to locate gemsbok calves, which only make up approximately 10% of the relatively thinly dispersed gemsbok population, but on which it relies heavily for food. The cats make up for their limited mobility by being able to catch a larger range of prey than the spotted hyena (Table 2). Additionally, cats typically hunt by stealth, employing a sit and wait or ambush foraging strategy, followed by a stalk and a short chase, whereas the spotted hyena follows a widely foraging and cursorial hunting strategy of running down prey over quite long distances.

Estimations of the average size of a meal for each species were calculated by assuming that the average mass of food from a kill was three quarters of the average size of an adult female of the species, summing the total for all kills, and dividing that by the number of kills recorded. The average travel distances between meals of over 1 kg for all species varied and is related to the average size of the meals (Mills, 2015). The solitary foraging brown hyena tends to find several small meals per night, whereas the spotted hyena and the lion eat fewer, but substantially larger meals which they often share with conspecifics. The sometimes social cheetah (males in coalitions or females with several cubs) and the more solitary leopard eat intermediate sized meals, although leopards move nearly twice as far as cheetahs do between meals.

Lion, cheetah and spotted hyena hunting success was similar, but leopard hunting success was lower. This might be the reason for the longer distances moved by leopards, but overcome to an extent by the leopard's broader diet (it has the most prey species making up more than 5% of its diet from the smallest kill sample). On the other hand, the leopard appears to exist at the lowest density of the large carnivores in the area, and therefore may be the least well adapted species to this habitat. As hunting plays an insignificant role in the brown hyena's foraging behavior it was omitted from this analysis.

Interspecific Relations

Because of the relatively low densities of the large carnivores in the arid Kalahari, interactions between the species are comparatively rare, but that does not necessarily mean that they are trivial.

The spotted hyena and the lion are potentially serious competitors, as they have the largest measure of overlap in diet and activity regime. Interactions between lions and spotted hyenas in the study area, although infrequent, are intense. Some interactions lasted over an hour, especially when initiated by spotted hyenas, as was the case in 64% of all the interactions observed. Food loss to either species was however uncommon.

When spotted hyenas were the initiators of an interaction, the impression gained was that they were attempting to move the larger competitors away from the area, and were prepared to take risks to achieve this. It seems that in the KTP spotted hyena/lion interactions are not as one-sided as they are in a highly productive area like the Ngorongoro Crater, where lions are clearly dominant (Kruuk, 1972). Perhaps in this arid region, where food resources are thinly distributed, the loss or gain of a kill is a more significant event. The smaller spotted hyena has more to lose if lions steal a kill in the arid Kalahari than Ngorongoro and, therefore, is more prepared to take the risk of standing up to lions. In two instances lions killed a spotted hyena cub, but spotted hyenas killing lion cubs was never observed.

The comparatively low spotted hyena density results in few interactions between them and leopards and cheetahs which mean that these cats lose little food to the spotted hyena. The brown hyena may lose food to the spotted hyena through being displaced from a scavenged carcass, although occasionally the two species were observed to share a carcass, at least briefly. Away from food spotted hyenas may harass brown hyenas and even occasionally kill one. However, the brown hyena outnumbered the larger and dominant spotted hyena by about 2:1 in the KTP, so the detrimental effects of these interactions are localized, and mainly take place in the vicinity of spotted hyena dens.

The numerical dominance of the spotted hyena in most African ecosystems is diminished in the arid Kalahari, and the rarer brown hyena is better able to survive in an area where food resources, especially large ones, are scarce. However, the fact that even in the arid Kalahari the spotted hyena appears to impact on the brown hyena, at least locally in the vicinity of spotted hyena dens, may explain the limited distribution of the brown hyena and its exclusion from areas of higher rainfall where spotted hyenas reach much higher densities.

The brown hyena derives considerable benefit by scavenging from lion kills in the KTP. Not only were 43% of the carcasses of known origin scavenged by brown hyenas killed by lions, the amount of food gained was relatively high, as these were large ungulates. On the other hand, lions may attack and kill or maim a brown hyena, but this is rare. On balance, it would seem that the brown hyena gains more than it loses from the presence of the lion in the arid Kalahari. In the case of the leopard, neither species is influenced by the presence of the other, but the cheetah is an important contributor of food to the brown hyena, especially along the riverbeds where springbok remains are frequently scavenged (Fig. 7). However, only 6% of cheetah springbok kills observed were kleptoparasitised by a brown hyena, and mostly the hyenas ate the remains after the cheetahs had departed. The diurnal hunting behavior of the cheetah, especially females with cubs, and the nocturnal activity regime of the brown hyena is a major reason for this; an example where temporal activity partitioning is important.

The cheetah (together with the wild dog) is often considered to be the most vulnerable of the large African carnivores to competition with larger carnivores, especially the lion and spotted hyena. However, although predation on small cheetah cubs in the KTP is high, lions and spotted hyenas were not found to be the major culprits and a range of smaller carnivores including black-backed jackals and honey badgers *Mellivora capensis* were suspected. Furthermore, energetically the cheetah is better able to deal with kleptoparasitism than the wild dog and the incidence of kleptoparasitism for cheetahs in the KTP is low; only 6.1% of carcasses were stolen, with an average percentage loss of meat of 65% per kill. Direct killing of cheetah adults by other carnivores was also found to be low; only two instances were observed, both by leopards, and both cheetahs were probably injured beforehand.

Interspecific interactions between carnivores has been held up as a major cause of density differences between large and smaller species. In Africa, this has been especially well illustrated in the case of the wild dog. However, the relative densities of carnivores are also determined by other factors. The availability of resources, not just biomass of prey (Hayward et al., 2007), but also the structure of the prey community is crucial. Arid ecosystems have a dominance of smaller-sized herbivores, while the more mesic savannah

Fig. 7 Brown hyena scavenging the remains of a springbok kill stolen from a cheetah.

ecosystems are dominated by larger-bodied herbivores. When these are in short supply, it may even up the differences in relative densities between large and smaller carnivores.

Conclusion

A major difference between the dynamics of large carnivore communities in mesic compared to arid savannahs like the arid Kalahari, is that larger carnivores are not the numerically dominate species in the arid systems as they are in the more mesic systems. Furthermore, the wild dog seems to be the first species to disappear as aridity increases, and the brown (and in the north, the striped) hyena appears. In this arid area the generalist brown hyena is numerically the dominate species.

Resource partitioning appears to be more acute in arid systems. Where prey is less abundant, dietary selection becomes more finely tuned, and each species tends to concentrate on the prey species and foraging strategy it is best adapted to utilize. For example, the cheetah, because of its superior acceleration, and ability to successfully follow the rapid twist and turns of fleeing steenbok, is the major predator of this wide ranging and common species in the arid Kalahari. The brown hyena, with its ability to move long distances, is the chief scavenger, whereas the spotted hyena hunts more and scavenges less than it does in areas where the brown hyena is absent. At the same time, some species show flexibility in diet and are able to make use of prey that, although abundant in other systems, are not often killed, for example, porcupines by lions and leopards, and springhares by cheetahs.

Interspecific relations between carnivores in arid systems may also take on a different dynamic than in more mesic savannahs. Whereas in the latter the largest and numerically dominant carnivores contribute the major share of animals killed across a wide size range, this is more equitably shared by the predator community in arid areas. Additionally, high rates of food loss by smaller carnivores (e.g. the Ngorongoro Crater) where lions stole much food from spotted hyenas has not been recorded in the arid Kalahari. The relationship between the lion and the brown hyena in the arid Kalahari is also an unusual example of a smaller carnivore deriving considerable benefit from a larger one.

Clearly arid regions are important habitat for large carnivores. Their flexibility to adapt foraging behavior and the varied nature of the relationships between the species are aspects of functional biodiversity that need to be conserved. Because of the extent to which arid regions cover Africa, more attention should be given to research and conservation in these areas. As has been pointed out by (Durant et al., 2014), the restoration of desert ecosystems will not only benefit biodiversity, it may also help to mitigate against global climate change where it leads to increasing aridity.

Abstract

The extreme of desert environments increases the challenges of conducting conservation activities for threatened species and biodiversity. The vast distances, inaccessibility, extreme temperatures, unpredictable weather, sparse population, time and costs all create a situation in which limited research or land management practice occur in many arid environments in Australia. In the Great Victoria Desert in Western Australia, a biodiversity offset trust was established to improve conservation outcomes for threatened species through research and landscape-scale on-ground land management practices. The costs and challenges associated with working in remote regions require conservation strategies that maximize available resources. We describe the conservation strategies employed by a small biodiversity offset trust to use funding, build partnerships and build knowledge to achieve positive conservation outcomes for two species, Sandhill Dunnart (*Sminthopsis psammophila*) and Malleefowl (*Leipoa ocellata*) in the Great Victoria Desert. These strategies are used as a means of overcoming the key challenges working in a remote arid region, lack of existing consolidated knowledge, expense and time of on-ground activities and lack of new knowledge.

Introduction

Achieving successful, sustainable conservation outcomes is challenging in vast, remote and sparsely populated areas (Jupp et al., 2015). The inaccessibility of remote deserts, lack of imperative, lack of resources, distance, time, weather extremes, climate variability and limited human resources create a situation in which understanding the biota of remote deserts in Western Australia is severely limited (Larson et al., 2009).

The Great Victoria Desert in Western Australia is one of the most remote and understudied regions in Australia (Fig. 1). Whilst knowledge of the biodiversity in the region is limited, the research which has been conducted demonstrates the region is an area of high biodiversity. There are over 1200 plant species recorded in the region, 51 of which are of conservation significance. There is one priority ecological community, which contains very high vertebrate diversity and unusual combinations of species (DBCA, 2017). The reptile diversity of the region is one of the highest in the world (Pianka, 1994). In terms of mammal and bird diversity, the area has a low diversity. There has been large loss of species, particularly mammals, from the region and a high proportion of the remaining species are threatened or vulnerable (Short and Smith, 1994; Woinarski et al., 2015).

The loss of species can be partially attributed to the lack of land management occurring across the region. Approximately 70% of the land tenure is unallocated crown land. This results in very limited funding available for government-led initiatives to take place on this land type. Approximately 25% of the land is Native Title, with Traditional Owners responsible for the land management practices. Government funding for the management of Native Title lands is also very limited. Increasingly Indigenous ranger positions are being funded by partnerships between Indigenous groups, environmental nongovernment groups and through the private sector to supplement government funding (Jupp et al., 2015). The remaining significant tenure in the Great Victoria Desert is Nature

Fig. 1 The Great Victoria Desert. Dark orange shows the Western Australian focus area, the light orange shows the size of the desert, as it stretches across South Australia.

Reserves, vested with the Department of Biodiversity, Conservation and Attractions. As with the other land tenure types, government funding is limited for work on Nature Reserves.

Two operational mines exist in the region, they occupy a very small percentage of the land tenure. Like many mining operations, the mines have a small physical footprint but an intense impact in the vicinity of the footprint. One mine in the region, Tropicana Joint Venture, established the Great Victoria Desert Biodiversity Trust (the Trust) as a means of offsetting the potential impacts of the mine. Biodiversity offsets are intended to create a “no net loss” or “net gain” for the species or biodiversity impacted by a development (Calvet et al., 2015). In this case, the offset was set as part of an environmental assessment under the *Commonwealth Environment Protection and Biodiversity Conservation Act 1999* which requires that any offset deliver a conservation outcome that improves or at least maintains the viability of the aspect of the environment that is affected by the proposal (DSEWPC, 2012). The offset was required because of potential impacts on three threatened species.

The constraints to traditional offsets that faced the mine were lack of knowledge on the threatened species potentially impacted and lack of biodiversity knowledge in the region leading to uncertainty over how offset funds could be best utilized for positive conservation outcomes for the threatened species potentially impacted by the mine. The offset was principally an indirect one with the establishment and funding of a Trust fund. The Trust was established with an independent management board, to use pre-determined funding to conduct research and on-ground management for the conservation of threatened species, focussing on the Sandhill Dunnart (*Sminthopsis psammophila*) and Malleefowl (*Leipoa ocellata*), in the Great Victoria Desert (Figs. 2 and 3). The mandate of the Trust also acknowledged that activities need to consider biodiversity and threats at the landscape level and to employ Traditional Owners where possible to conduct land management activities.

Fig. 3 Malleefowl (*Leipoa ocellata*).

We outline the processes and strategic principles involved in achieving successful conservation strategies when working in a remote, inaccessible, sparsely populated region, with limited funding. Examples of the projects and activities initiated under these strategic conservation principles are also described. Key strategies include actively engaging with a variety of stakeholders in the region, building partnerships, building on foundational efforts and developing projects that meet multiple objectives. These techniques are recognized as important features of conservation and natural resource management in Australia (Fitzsimons et al., 2013).

Method

Stakeholder Engagement and Partnerships

Successful conservation activities should acknowledge that different groups and organizations have different strengths and understandings of threatened species and biodiversity in the region. Finding appropriate ways of engaging with these stakeholders and building partnerships to create a collaborative approach is critical to the success of projects in remote areas. Stakeholder engagement delivers multi-faceted benefits, not only do groups build new knowledge whilst building new relationships. It also increases stakeholder trust, ownership and ability to act. Meaningful engagement can lead to better quality decisions, reduce conflict, increase the likelihood of success for a project and reduce implementation costs through cost sharing or in-kind support (Sterling et al., 2017).

Experts in the field

Working in a region with limited stakeholders, limited and dispersed knowledge and limited funding necessitates working closely with all stakeholders to maximize the benefits and utilize the strengths and knowledge of different actors. In 2014 the Trust held a series of workshops on threatened species in the region. The aim of these workshops was to bring together experts who had knowledge of the threatened species and work conducted in this remote region. By bringing together key actors, the latest information was attained. As a group, experts were also able to discuss the gaps in their collective knowledge. By examining existing knowledge and knowledge gaps, the groups were able to determine the next key funding priorities for threatened species. Bringing together experts and reaching consensus on the next steps required gave the Trust a strong mandate for funding future projects.

Adaptive Management Partners

Whilst the threatened species in the region were the primary focus of these initial workshops, engagement continued at a broader landscape level concurrently. Threatened species exist within a broader landscape and whilst there many knowledge gaps for particular species, the broad level threats, effecting biodiversity and ecosystems in the region are also threatening processes for individual species. The principle threats are recognized as predation by introduced species particularly the feral cat, *Felis catus*, and the European Red Fox, *Vulpes vulpes*, and altered fire regimes (Woinarski et al., 2015). To address these broader landscape level threats, the Trust partnered with key land managers and stakeholders in the region. These groups included Traditional Owner groups, the Western Australian Department of Biodiversity, Conservation and Attractions, Rangelands Natural Resources Management, Greening Australia and Central Desert Native Title Services. These groups each brought an array of different knowledge of the region as well as different priorities in terms of the perceived threats to biodiversity. Over the course of three formal workshops, groups were able to work together through the Conservation Action Planning process to, as a group, assess which threats or assets were in immediate need for action and which threats or assets were of lower priority. Working through this process collectively, the group prioritized actions on known threats and also identified additional landscape threats. These threats included the likely loss of the unique Traditional Ecological Knowledge (TEK) and cultural knowledge in the region and the threat that buffel grass (*Cenchrus ciliaris*) invasions posed to biodiversity by fuelling large, intense bush fires. The result of this Adaptive Management Partnership was the successful funding of several projects including funding for a cultural and biodiversity trip by Traditional Owners, fire scar mapping projects and funding for buffel grass (*C. ciliaris*) management.

After the initial meetings and funding of projects, outputs from the partnership have slowed. Changes in personnel, lack of leadership and lack of direction has resulted in limited meeting of the “Adaptive Management Partners” as a formal group. The plan created by this process, whilst referenced by different groups, has not effectively been “owned” by any of the key stakeholders. Whilst the lack of ongoing structured meetings and lack of ownership of the plan may make the project appear unsuccessful, regular interactions still occur between different members of the group and therefore process has resulted in strong relationships between the organizations.

Mining and exploration operations

Mining and explorations operations in the Great Victoria Desert represent one of the few industries operating in the region. These operations have the potential to have a significant impact on biodiversity through direct disturbance to the environment and through the introduction of waste outputs (food/garbage, etc.). These impacts may increase the number of scavenger species (feral dogs, cats, foxes, mice and rats) in the area which in turn negatively impact on the biodiversity of the area (Sonter et al., 2018). Mining operations also come with a number of environmental regulatory conditions and the requirement to conduct environmental surveys to determine what species are present in a particular area. With limited other funding available, the surveys and data collected by these operations represent a key resource for understanding the biodiversity of the region. Working in partnership with mining and exploration industries has been a key component of understanding biodiversity in the region. The Trust has actively informed mining companies of its activities and worked with them to share knowledge and resources. The Tropicana Joint Venture, has provided a large amount of in-kind support to Trust funded activities by providing access to their village and facilities, food and equipment and use of transportation resources. This has allowed projects to be undertaken at a significantly reduced cost or in some instances, made possible projects that would have otherwise been logistically near impossible. Vimy Resources, another mining operation in the region, has actively shared their methods for camera trapping Sandhill Dunnarts including their process for refinement and improvement of standard camera trapping techniques. Partnering, knowledge sharing and in-kind support are vital contributors to achieving outcomes in a region as remote and inaccessible at the Great Victoria Desert.

Traditional Owners

Engagement and collaboration with Traditional Owners is a vital part of any environmental work undertaken in Australia. In the Great Victoria Desert, where the Traditional Owners are the only permanent residents on-country, this collaboration is even more vital. Traditional Owners have a unique knowledge of country and species. They also have an extremely long connection to the land and Elders are able to describe changes that have occurred in the landscape in terms of weather, plants and changes in animal populations. Valuing the knowledge and skills of Traditional Owners and integrating it with western science deepens the understanding of the land, species and changes that have been occurring over many millennia (Horstman and Wightman, 2001).

One project undertaken to support Traditional Owners involved facilitating Traditional Owners access to their sacred cultural sites. In this region, distance and lack of vehicle access has prevented many Traditional Owners from visiting their cultural sites of significance. This means that whilst Elders know the sites and their significance, they have not been able to pass this cultural knowledge onto younger generations. The inability to visit sites also means that the sites are not being protected from bushfire and their current status is unknown. The uncertainty over the sites results in lack of action in terms of management, as Elders and Traditional Owner Ranger teams are reluctant to conduct activities which may adversely impact on the sites. The Trust provided funding to allow Elders and Traditional Owner Ranger teams to access sites using helicopters. This allowed the Traditional Owners to visit sites in a relatively fast manner and pass on traditional knowledge to younger generations. The Indigenous Ranger teams also used technology to map the biodiversity of these cultural sites. Using iPads and an application called *Fulcrum* rangers were able to photograph sites, document species and conditions of the site and conduct biodiversity assessments of the areas.

The project met two primary objectives, facilitating the transfer of TEK and cultural knowledge as well documenting the sites and assessing the need for landscape management activities. Understanding the priorities for Traditional Owners and utilizing western science and technology alongside these priorities can create opportunities for comanagement in which all groups benefit (Zurba et al., 2012).

Collaborations and knowledge sharing

Whilst formal partnerships are essential for some projects, ongoing collaborations and knowledge sharing with any actors in the region is vital. With limited research being undertaken and limited on-ground work being conducted, maximizing the knowledge that anyone is conducting in the region is essential. Regular contact with organizations known to be working in the region is the most simple and direct means for knowledge sharing. Outside of known organizations, determining who is working in the region and where they are working is more challenging. The Trust reviews databases (e.g., TENGGRAPH from the Department of Mines and Petroleum) to see which companies hold tenements (mining and exploration) in the region. The Trust also hold workshops and invites a wide range of stakeholders to participate in knowledge sharing sessions, these workshops include regulatory agencies who may have a clearer picture of who is undertaking work and the type of work being conducted in the region.

Building on Existing Knowledge/Maximum Utility of Funds

Biodiversity conservation plan

In remote areas, where funding and access are limited, it is vital that existing knowledge of biodiversity is known and utilized. In the Great Victoria Desert, research has been conducted over a number of decades, across a variety of species and in a wide array of locations. As part of its mandate, the Trust completed a “biodiversity conservation plan for the Shield and Central regions of the GVD.” This document compiled the available information to create a baseline of knowledge for the region and is expected to evolve as more research and studies are undertaken in the region.

Desktop studies

In order to thoroughly investigate projects before funds are expended on costly on-ground activities, the Trust initiated a series of desk top studies on Sandhill Dunnart and Malleefowl and fire effects, considered to be one of the greatest threats facing these species. For the two threatened species, the Trust funded projects that focussed on examining all known location records, detailing the habitat preferences and determining which areas were suitable for the species. The Trust also funded research into the best methods for surveying for these species. These desktop studies have enabled the Trust to fund on-ground surveys using the best available techniques. These surveys have used the data to search locations in which the species have a high likelihood of being present as well as search locations which could re-shape knowledge of the species if the species were detected in habitat previously determined to be “unsuitable.”

Remote sensing

Intense fire is one of the critical threats facing the Great Victoria Desert. Whilst fire has always been part of the desert ecosystem, the scale and intensity of fire in the Great Victoria Desert has increased at a dramatic rate (Burrows and Chapman, 2018). The Sandhill Dunnart and Malleefowl habitation are principally associated with long unburnt areas (Davis et al., 2016; Moseby et al., 2016). Habitation typically occurs in habitats that are over 10 years unburnt (Moseby et al., 2016). In order to determine the locations of long unburnt areas, the Trust funded a project to detect the fire scars in the landscape for the last 20 years (from 2000 to present). This project has allowed stakeholders the ability to interrogate areas of the Great Victoria Desert for fire scars including recent fires. The accuracy of the fire scar data has been questioned however the datasets are likely to provide fire data at a broad level.

In the Great Victoria Desert, the fire landscape was thought to have changed when the Traditional Owners were removed from the region. To investigate fire patterns under traditional management versus contemporary fire regimes, with virtually no fire management, the Trust commissioned a project to examine the earliest available records of the region. The result was an analysis of photography from 1960/61, shortly after the removal of Traditional Owners from the region (Burrows and Chapman, 2018). The fire scar imagery in 1960/61 showed mean and maximum fire scars of 11.2 ha and 3953 ha respectively. The mean and maximum fire scar size over the 17-year study period (2000–17) was 3699 ha and 1,033,121 ha, respectively (Burrows and Chapman, 2018). The result of this study is the need for reinstating smaller, low intensity, mosaic fires in the landscape in order to increase biodiversity and attain vegetation of diverse ages.

Multipurpose On-ground Efforts

Camera studies

In order to investigate a large number of areas where research had not previously been conducted the Trust funded camera studies across large areas of the Great Victoria Desert. The locations were selected based on a design for testing Sandhill Dunnart habitat preference. The design was based on a number of variables but principally designed on habitat deemed “suitable,” “moderately suitable” and “unsuitable” for Sandhill Dunnarts. Twenty random locations across the Great Victoria Desert encompassing these three habitat preferences and cameras were set up for 30 days. The aim was to detect Sandhill Dunnarts but also what other species were present across the desert. The result was the detection of Sandhill Dunnarts at two possible locations and detection of a range of native and feral species.

Alongside the cameras the contractors also conducted searches to determine evidence of other species (tracks, nests, burrows, etc.). Significant numbers of other species were detected and the data are available for analysis by researchers seeking to interrogate it for timings, numbers and species and the correlations between them.

Pitfall trapping and long walks

To investigate the possible Sandhill Dunnart locations, detected in the camera studies, contractors conducted two trips to the locations. The first trip was to dig pitfall traps and place out arrays of cameras at these two sites. Habitat assessments were also conducted. During the second trip camera data was collected and pitfall traps were opened. Species captured in the pitfall traps were recorded each day for a week. During the day, contractors conducted “long walks” to detect Malleefowl in the region. Long walks are a technique recognized for detecting Malleefowl in arid areas, where distances between Malleefowl mounds are likely to be large. This technique allows large distances to be searched over a relatively short period of time. The walks were conducted in areas that previous desk top studies had deemed as “highly suitable” for Malleefowl. Combining multiple techniques when searching for a species allows for documenting a wide variety of species, whether through direct capture, camera detection or sightings or evidence of species.

Conclusion and Key Challenges

We highlighted a number of key challenges in working towards positive conservation outcomes in remote desert regions. Firstly, knowledge of biodiversity in desert regions can be dispersed among diverse experts and across decades in terms of research. Creating forums to bring together this expertise can work well in discrete events as a “knowledge capture” however building and sustainable long-term collaborative partnerships takes time, effort, resources and the ability to effectively engage stakeholders to take shared ownership of a project. Maintaining motivation and drive, when stakeholders are located in geographically distant locations, with limited resources and competing priorities, can lead to ebbs and flows in engagement. Regular interactions with stakeholders, through any available mode can help to maintain a relationship through periods when the project priorities are not that of individual stakeholders. The location of the Trust, in the capital city of Perth, is a potential constraint to achieving successful outcomes. Whilst several key stakeholders are also based in Perth, this makes the distance to the region and to actual land managers very large, limiting the amount of time Trust staff spend on-ground in the Great Victoria Desert. This is a barrier to building trust with on-ground land managers.

A second challenge to achieving positive conservation outcomes in remote desert regions is the distance away from population centers, creating large costs involved in the mobilization of any on-ground project. To minimize these costs, where possible, research can be conducted using desktop studies and remote sensing. This can allow researchers to access the best available information and help shape and define parameters for future on-ground projects. A positive is that this creates opportunity and motivation to engage with and utilize the Traditional Owners living on Country, which not only provides useful data but also helps establish positive working relationships and provides additional financial support for them to stay on Country.

Finally, the limited scientific biodiversity knowledge of many desert regions is a key challenge for creating positive conservation outcomes. This lack of knowledge necessitates that any on-ground activities that do occur should capture as much data as possible during the time in the field, including of non-target species. A key criterion the Trust now uses when considering funding projects is the nature and extent of opportunistic data collection that can be carried out. This issue of limited scientific biodiversity knowledge has bought the Trust’s attention to the need to collect the knowledge of the Traditional Owners living on Country.

The conservation strategies we outlined in this paper are the some of the initial strategies employed by the Trust to increase knowledge, build partnerships and commence on-ground research on threatened species and biodiversity in the region. The next steps for the Trust and its partners will be ensuring on-ground action that delivers conservation benefit to the threatened species and biodiversity of the region. Monitoring any on-ground action, evaluating the success of interventions and then adapting projects based on learnings are the key next steps for the Trust. Success will be measured not only by positive outcomes for the species and reductions in threats, but by the strength of partnerships, the trust among partners, utilizing appropriate technologies and desktop studies where appropriate and attempting to get the most multi-purpose knowledge gain from any on-ground activities. The extremes and challenges of the desert environment may mean that longer time frames are needed to achieve results but they can be achieved when holistic conservation strategies are employed.

Abstract

The Mojave Desert is a vast and diverse landscape in the southwestern United States, encompassing 127,689 km². This ecoregion is bordered by the colder and wetter Great Basin desert to the north, and the warmer and wetter Sonoran and Chihuahuan deserts to the south. Spanning from 86 m below sea level at Badwater Basin in Death Valley, California, to 3632 m at its highest mountains near Las Vegas, Nevada, the Mojave is the driest of the four North American deserts, in part due to the rain-shadow caused by the Transverse Ranges on its western edge. Extremes of moisture availability, temperature, physiographic variety, and soil diversity all are key in the formation of this unique landscape, and the divergence of its inhabitants over time. While the Mojave is often considered an intermediary with respect to the plants and animals that occupy the Great Basin and Sonoran Deserts, there are many species unique to the Mojave that aid in highlighting its unique characteristics. The Joshua Tree, Mojave Desert Tortoise, Mohave ground squirrel, and several species of fringe-toed lizards are all endemics to this ecoregion that have adapted to this austere environment. There is also a wide array of fishes and aquatic invertebrates that occupy the Mojave's sparse and discontinuous waterways and springs. Nearly all of these Mojave endemics are the subjects of conservation concern facing a rapidly changing environment driven by increasing human populations and land use, and a changing climate.

Introduction

The biogeography of the Mojave involves the interaction of geography, ecology, and physiology as shaped by the temporal changes of geology and climatic conditions. The Mojave is a broad desert landscape, with complex topography, and a harsh and unforgiving climate, both of which have a dynamic history of change during the assembly of the flora and fauna that inhabit the region. Vicariant events have isolated and rejoined the flora and fauna of the region, and allowed and facilitated the immigration of new species into the region. Thus, the Mojave flora and fauna are an assemblage composed of a combination of species that pre-date the region as a desert environment, and others that have migrated into it relatively recently. Below we describe the Mojave in a brief historical context of its location, its geological history, and the species that characterize its flora and fauna, including species unique to the Mojave. We discuss the conditions under which those species arrived in the Mojave, and the current challenges to their persistence.

Where Is the Mojave Desert?

The Mojave Desert ecoregion encompasses approximately 127,689 km² in the southwestern United States of America ranging from southern California—through southern Nevada to southwestern Utah, and northwestern Arizona (Fig. 1). This smallest of North American deserts, is often considered an intermediate between the Great Basin Desert immediately to the north and the Sonoran Desert to the south (MacMahon and National Audubon Society, 1985; Turner, 1994a). Encompassing Death Valley National Park (NP), the Mojave includes the lowest elevation site in North America ensuring infamy as the hottest and driest place in North America. This hot-temperate desert is typified by a basin and range topology with low broad valleys interspersed by abruptly rising mountain ranges that result from block fault dynamics.

Fig. 1 The Mojave Desert and surrounding deserts, located in the southwestern United States.

The westernmost point in the Mojave occurs at the apex of a sideward-leaning 'V' at the convergence of the San Andreas, and Garlock Faults in southern California, at Tehachapi Pass between the San Gabriel Mountains in the Transverse Ranges and Tehachapi Mountains at the southern extent of the Sierra Nevada Range (Fig. 2). The northern boundary of the Mojave merges in a broad ecotone with the cooler/higher elevation Great Basin Desert (MacKay, 2013), from Death Valley Wash, California, through the Pahrangat Valley, Nevada, to St. George, Utah (Fig. 1). The ecotone undulates across the generally north-south oriented basins that commonly contain remnants of pluvial lakes, which have since dried, leaving behind saline lake bottoms (playas, Bowman, 2019), or extensive wash systems (now only intermittently wet). The Mojave is bounded by the Colorado Plateau in the northeast, southward to the mouth of the Grand Canyon, Arizona, and Hualapai Valley (Fig. 1). Along its southern boundary, the Mojave intergrades with the Sonoran Desert near Wikieup, Arizona, and then southwest toward Needles Arizona. Across the Colorado River, at Needles, California, the Mojave comes into contact with the Colorado Desert through the Eagle Mountains to the Morongo Valley, where it merges with the western mountain ranges (Fig. 1).

The Driest, Hottest, Place in North America

In California, prevailing winter atmospheric low pressure systems from the Pacific Ocean draw warm moist air from the south providing winter rains. However, before the winter storms reach the Mojave, the high mountains of the Pacific Cordillera draw moisture from the atmosphere due to orographic lift, creating a rain-shadow that renders the Mojave as the driest of the North American Deserts. The northwest extent of the desert, near Bishop, California is in the depth of this rain shadow, and what little precipitation occurs, is dominated by winter storms during October through May. Starting at -117° longitude, near Barstow, California and in the middle of the Mojave, a gradient toward bi-seasonal precipitation increases (Hereford et al., 2006) as summer storms of tropical origin move northward from the Gulf of California, and the Pacific from June through September. Isolated desert mountain ranges separated by deep valleys create localized orographic uplift that cools the moisture laden tropical flows resulting in highly variable and often violent summer storms. These summer storms add to the annual precipitation totals in the region that are low (regional mean 137 mm/yr) and range from 34 to 310 mm/yr (Hereford et al., 2006).

Mojave Desert precipitation is also highly variable among years and decades. This climate pattern is influenced by fluctuations in surface water temperatures in the Pacific Ocean known as the Southern Oscillation Index (SOI). Over the last century there have

Fig. 2 Prominent Faults and vicariant features of the Mojave Desert.

been many extended periods of drought, including 1893–1904, 1940–75, and 1989–91 interspersed by wetter periods (Hereford et al., 2006). This pattern of dry and wet periods creates pulses of resource availability that are a driving force for plant and animal population dynamics across the Mojave, and other arid ecosystems (Schwinning et al., 2004), although these effects on animal populations are asynchronous, and extremely complex (Brown and Morgan Ernest, 2002; Greenville et al., 2016; Thibault et al., 2010).

Temperatures in the Mojave are notoriously extreme, but also highly variable—given the ranges of elevation encompassed by the Mojave (Redmond, 2009). Summer temperatures are highest in the lowest portions of Death Valley, where air temperatures in July can average in excess of 47 °C with soil surface temperatures of 62 °C, and average day and night temperatures can differ by ~ 29 °C (Redmond, 2009). Extreme temperatures in the western Mojave range between – 9 °C to 57 °C (Bai et al., 2010) and in the Northeastern Mojave have been reported to have similar extremes (– 19 °C to 46 °C; Beatley, 1974), while average air temperatures for the western Mojave range between – 0.5 °C to 38 °C, and average temperatures in the eastern Mojave are 2.2 °C and 40 °C (Germano et al., 1994). These extreme temperatures readily evaporate summer precipitation on the warmest days, creating stress on desert plants (Munson et al., 2015; Redmond, 2009). Average soil temperatures at –0.5 m are linearly related to elevation, and range between 12 °C and 30 °C (Bai et al., 2010). Temperatures in the Mojave have been increasing since the 1970s (Redmond, 2009), and these changes have resulted in differential persistence in perennial plant composition (Munson et al., 2015). With increasing temperatures, and reduced rainfall predicted in the future (Cayan et al., 2010), there may be yet unforeseen shifts in desert plant community composition (Munson et al., 2015), that may have cascading effects on the entire ecosystem.

Vegetation

Owing to the harsh environmental conditions, the Mojave Desert is a land nearly devoid of trees. The shrubby vegetation types in the Mojave are generally sparse, with vegetative cover between 45% and 15% or less over large expanses. Plant species distributions in the Mojave vary in association with climate, parent soil, soil texture, landscape position (correlated with hydrology, temperature, and particle size), biological interactions, and historical biogeography. The flora of the Mojave is diverse, with upwards of 2600 plant species in the desert within California alone (MacKay, 2013). Some of the plant species that typify the Mojave are shared with the other North American deserts (Turner, 1994a), and while there is greater overlap of growth forms and species with the Sonoran and Chihuahuan hot deserts, there is also overlap among species with the colder Great Basin Desert. Considering the area covered, the Mojave is largely dominated by a creosote/white bursage (*Larrea tridentata*/*Ambrosia dumosa*) scrub alliance—which is inter-mixed with other prominent flora (Barbour et al., 2007). This association is not unique to the Mojave and is largely shared with the Sonoran desert flora—except for the replacement of white bursage for triangle-leaf bursage (*Ambrosia deltoidea*). The southern

boundaries of the Mojave thus can be difficult to identify (Turner, 1994a). However, to the east of the Colorado River, the giant saguaro cactus (*Carnegiea gigantea*), indicates the ecotone with the Sonoran Desert, and west of the Colorado River, the smoke tree (*Psoralea argemone*) indicates the ecotone with the Colorado Desert.

At the northern boundaries of the Mojave and Great Basin desert, ecotones occur where stands of blackbrush (*Coleogyne ramosissima*), a prominent shrub in the upper elevations and northern regions of the Mojave, transitions to areas dominated by several species of Sagebrush (*Artemisia* spp.; Richardson and Meyer, 2012). Biogeographically, the plant communities of the Mojave are of recent origin, following major climatic changes during the Pleistocene and Holocene (Barbour et al., 2007; Koehler et al., 2005; Spaulding, 1991). Joshua trees (*Yucca brevifolia*, and *Yucca jaegeriana*) are endemic to the Mojave, and are thought to be among the most characteristic plants defining the Mojave (Lenz, 2007). These species are not distributed ubiquitously across the desert, but rather tend to be found in cooler/higher and more northerly upland habitats, in mixed Mojave desert scrub communities, and are largely absent from the lower elevation desert basins and southerly regions (Coville and Clark, 1893; Rowlands, 1978; Turner, 1994a). Vegetation in the desert typically occurs in zones driven by temperature, precipitation, and soil types, all of which covary with elevation (Merriam, 1890; Beatley, 1976).

Shrublands

Shrublands are comprised of several plant growth forms with widely dispersed perennial woody and herbaceous plants, succulents, geophytes, and annual plant species comprising the majority of land surface. Starting at the lowest elevations and from the playa edges, in closed basins, the Saltbush Scrub Community is most common due to the tolerance of its community members to higher salt content (halophytes). This community is typified by several species of saltbush (e.g., *Atriplex canescens*, *A. confertifolia*, and *A. polycarpa*), but also includes hop-sage (*Grayia spinosa*) and winter fat (*Krascheninnikovia lanata*), among others (MacKay, 2013; Turner, 1994a).

Upslope from the playa, are the extensive shrublands of the middle or upper bajada (a regional name for outwash plains composed of alluvial deposits, Bowman, 2019) where habitats typically have warmer temperatures, and plant associations vary widely depending on soil composition and depth, temperature, and precipitation patterns and amounts (Barbour et al., 2007). Creosote/bursage (*Larrea tridentata* and *Ambrosia dumosa*) are frequently dominant members of the plant community here, and alluvial slopes and fans comprise much of the Mojave landscape. This plant association co-occurs in four major plant alliances across a broad elevational gradient and topologies including bajadas, washes, toeslopes, hillsides, and rocky slopes (Barbour et al., 2007). Other plants associated with this vegetation alliance include many shrub species (e.g., brittlebush—*Encelia farinosa*, Anderson boxthorn—*Lycium andersonii*, saltbush species—*Atriplex* spp., joint-fir—*Ephedra nevadensis* and *E. californica*), cacti (beavertail prickly pear—*Opuntia basilaris*, Mojave mound cactus—*Echinocereus triglochidiatus*, and chollas—*Cylindropuntia* spp.), and yuccas (Mojave yucca—*Yucca schidigera*).

On the upper bajada creosote/bursage scrub communities can be more diverse (than lower elevation sites), coinciding with cooler temperatures, higher rainfall, and frequently shallower soils. This zone is frequently called “Mixed Mojave desert scrub,” and contains visually dominant yucca species. Yucca composition changes with elevation across this upland habitat, where Mojave yucca (*Yucca schidigera*) occurs in lower elevations, followed by a mix with Joshua trees (*Y. brevifolia* and *Y. jaegeriana*), and Banana yucca (*Y. baccata*) replacing other yuccas at higher elevations, where they are thought to compete for water resources (Yeaton et al., 1985). Localized areas can be densely populated in savannah-like communities described as “Joshua Tree woodlands.” These communities typically have an understory of creosote bush, cheesebush (*Hymenoclea salsola*), and jointfir (*Ephedra* spp.) among other species of Yucca (*Y. schidigera* and *Y. baccata*). Joshua tree woodlands typically transition into Blackbrush habitat at higher elevations. While the Joshua tree can dominate landscapes visually, their dominance has been said to be of stature only (Turner, 1994a), as they “contribute little in a quantitative sense” to vegetation abundance (Rowlands, 1978). However, Joshua tree stands can become quite dense, as seen in areas like Joshua Tree National Park and Mojave National Preserve in California, the Wee Thump Joshua Tree Wilderness Area in Nevada, the Grapevine Mesa Area of Critical Environmental Concern in Arizona, and Joshua tree Highway (along Hwy 93 from Wikieup to Wickenburg, Arizona).

Blackbrush shrublands and rare stands of sagebrush (*Artemisia* spp.—i.e., near bishop, CA; Spring Mountains, NV; and south of St. George, UT—Richardson and Meyer, 2012) represent the highest elevations/latitudes of shrublands in the Mojave desert biome—as they are tolerant of cooler temperatures, but are absent from higher elevation basins where low temperature extremes may limit their distribution (Turner, 1994b) and from areas of higher rainfall (Beatley, 1976). In such areas, low temperature extremes likely limit the presence of creosote bush (Beatley, 1974), and thus blackbrush can occur in near monocultures at upper elevations (Barbour et al., 2007). Mojave blackbrush communities also include jointfir (*Ephedra* spp.), Joshua tree, and spiny hopsage.

At higher elevations within the Mojave, with even cooler temperatures and more rainfall, conifer woodlands intermix with chaparral species at lower elevations, and pine forests to alpine habitats at upper elevations. The woodlands are characterized by juniper (*Juniperus* spp.) and piñon pine (*Pinus* spp.), with transitional interior chaparral species, for example, oaks (*Quercus* spp.), manzanita (*Arctostaphylos* spp.) and mountain mahogany (*Cercocarpus ledifolius*). While not common in the Mojave, several of the higher mountain ranges (e.g., the Spring and Sheep ranges within southern Nevada) include habitat transitioning to Mixed Conifers (e.g., ponderosa pines—*Pinus ponderosa*, white fir—*Abies concolor*) and even to bristlecone pine (*Pinus longaeva*; Charlet, 1996), and alpine habitats on the peaks of the highest ranges in Clark County, Nevada (Clokey, 1951). Similarly, Telescope Peak and the

Panamint and Argus ranges in Death Valley, CA have similar community types including pine woodlands, bristlecone pine, limber pines (*Pinus flexilis*) and other tree species (e.g., mountain mahogany, *Cercocarpus*; Barbour et al., 2007).

Riparian Habitat

The rare trees found in the Mojave generally only exist in riparian habitats, where surface water flows along major river systems (e.g., Colorado River, Virgin River, Muddy River, Amargosa River, and Mojave River), and rare desert oases where artesian springs spill out into the desert. Xeriparian habitats (also known locally as washes or arroyos) are more common than riparian habitats, and exist only where watercourses flow intermittently. Xeriparian trees (e.g., catclaw acacia—*Acacia greggii*, desert willow—*Chilopsis linearis*) are generally smaller than those found in riparian habitats. Both types of riparian habits also support a variety of shrubby and herbaceous plant species and are important as cover and food resources for a tremendous variety of wildlife including migrating birds.

Riparian habitats in the Mojave are among the rarest habitat type, but are high in diversity of plants as well as animal species, and these serve as vital habitat for many birds. Riparian areas are inhabited by several tree species (e.g., cottonwood (*Populus fremontii*), willow (*Salix* spp.), velvet ash (*Fraxinus velutina*), honey mesquite (*Prosopis glandulosa*) and screwbean mesquite (*P. pubescens*) that provide important habitat structure and shelter for nesting birds (Fleishman et al., 2003), and foraging habitat for several species of bats (Williams et al., 2006). Birds occupying riparian habitats are the subject of much conservation concern, including Yellow-Billed Cuckoo (*Coccyzus americanus*), Arizona Bell's Vireo (*Vireo bellii arizonae*), Le Conte's Thrasher (*Toxostoma lecontei*), Phainopepla (*Phainopepla nitens*), Costa's Hummingbird (*Calypte costae*), Southwestern Willow Flycatcher (*Empidonax traillii eximius*), and Yuma Ridgway's Rail (*Rallus obsoletus yumanensis*), among others (Austin, 1970).

Invasive plant species in desert riparian systems have been the source of much concern, among the most notorious are Salt Cedar (*Tamarix ramosissima*, and *T. athel*), which have invaded most of the riparian systems in the Mojave (Fleishman et al., 2003; Sogge et al., 2008). While this species displaces many of the native tree species, many bird species appear to use it effectively for their nesting and cover needs, and there is concern that the removal of structural function during restoration efforts may cause unwanted impacts to sensitive bird species (Fleishman et al., 2003; Sogge et al., 2008).

Mojave Desert Fauna

Mojave desert species are renowned for the variety of ways that they adapt to the harsh environmental conditions found there. Many desert animals avoid extremes of heat or cold by avoiding those conditions in subterranean or vegetative cover sites, and only being active for relatively short periods of time on a daily, seasonal, or annual basis. Desert tortoises vary their daily activity periods according to temperature windows that meet their physiological limits (Zimmerman et al., 1994). Mohave ground squirrels are active during a very short period of time during April through June each year, when they glean all of their nutritional needs, and reproduce (Best, 1995). The desert slender salamander (*Batrachoseps major aridus*) is active only during wet winter periods, and otherwise very difficult to find (Duncan and Esque, 1986). The silky flycatcher (*Phainopepla nitens*) is a bird that lays its eggs and raises its young beginning in later winter (February) when its host plant desert mistletoe (Chu and Walsberg, 1999) flowers and attracts nitrogen rich insects to feed its young, then they all leave the desert during the summer. There are also many anatomical and physiological means of coping with desert conditions. Jackrabbits (*Lepus californicus*) use evaporative cooling of their nasal area combined with vasoconstriction in their extravagantly long ears to assist in cooling their brains (Caputa et al., 1976). Kangaroo rats (*Dipodomys* spp.) have tortuous nasal passages causing the water vapor in their breath to condense in those passages reducing water loss (Schmidt-Nielsen and Schmidt-Nielsen, 1951). Some desert fishes exist in hypersaline desert hot springs (McClanahan et al., 1986). During cold desert nights, the herbivorous desert chuckwalla lizard (*Sauromalus ater*) maintains a high body temperature that is required by its symbiotic gut microflora by seeking out and hugging rocks that retain high temperatures deep into the night (Zimmerman and Tracy, 1989). Following is a description of some of the diverse groups of desert animals.

Although biologists have conducted biological surveys of the Mojave Desert since the late 19th century (Fisher et al., 1893), there is not a complete accounting of mammals present. Furthermore, most resident species occur across multiple desert biomes. However, recent surveys (using a combination of museum records, field censuses and literature reviews) of the five Mojave national parks (Death Valley NP, Joshua Tree NP, Manzanar NHA, and Mojave National Preserve, CA; Lake Mead NRA, NV) identified ~128 unique species of mammals potentially inhabiting the parks collectively, and average of 70 unique species within individual parks (Drost and Hart, 2008). The national parks represent a range of habitats that typify extant Mojave habitat types, and thus the species encountered there are likely to be an ample representation of mammal diversity in the Mojave. Herbivores and granivores include rodents such as the kangaroo rats (*Dipodomys* spp.), pocket mice (*Perognathus* spp.), pocket gophers (*Thomomys* spp.), woodrats (*Neotoma* spp.), lagomorphs (black-tailed jackrabbit—*Lepus californicus*, and desert cottontails—*Sylvilagus auduboni*), squirrels (*Ammospermophilus leucurus* and *Xerospermophilus mojaviensis*), and ungulates (desert bighorn—*Ovis canadensis nelsoni*, mule deer—*Odocoileus hemionus*, and pronghorn—*Antilocapra americana*). Insectivores include desert shrews (*Notiosorex crawfordi*) and bats (Vespertilionidae). Carnivores include western spotted skunk (*Spilogale gracilis*); kit fox (*Vulpes macrotis*); coyote (*Canis latrans*); American badger (*Taxidea taxus*); and mountain lion (*Puma concolor*).

Only a single avian species, LeConte's Thrasher (*Toxostoma lecontei*), is considered a Mojave specialist (Turner, 1994a), and it attracted the attention of ornithologists from the earliest explorations of the region due to its unexpected breadth in distribution and

niche (Fisher, 1893; Grinnell, 1933). Flight provides birds the opportunity to migrate seasonally to escape harsh northerly winter conditions, or inhospitable summer conditions locally, track resource fluctuations to breed in the most productive areas, or simply pass through from more northerly or southerly locations when resources are most abundant in the spring or fall. Resource-rich areas such as riparian areas, mesquite bosques, or urban islands of habitat can provide migrants important rich locations for cover and resource acquisition in an otherwise 'desert' of resource availability. Such locations are referred to as 'bird traps' because once known, these areas of elevated diversity and density during inclement conditions along migration routes can be visited by researchers or bird enthusiasts reliably to observe a diversity of species (Paxton et al., 2008). Representative Mojave Desert birds include: Black-throated Sparrow (*Amphispiza bilineata*); Rock Wren (*Salpinctes obsoletus*); Silky Flycatcher (*Phainopepla nitens*); Horned Lark (*Eremophila alpestris*); Loggerhead Shrike (*Lanius ludovicianus*); LeConte's Thrasher (*Toxostoma lecontei*); Common Poor Will (*Phalaenoptilus nuttallii*); House Finch (*Haemorhous mexicanus*); Roadrunner (*Geococcyx californianus*); Common Raven (*Corvus corax*); Turkey Vulture (*Cathartes aura*); Red-tailed Hawk (*Buteo jamaicensis*); Burrowing Owl (*Athene cunicularia*), and Golden Eagle (*Aquila chrysaetos*).

Reptiles are distributed across the landscape in a mosaic of habitats—some as generalists, such as side-blotched lizards (*Uta stansburiana*) found almost anywhere having shrubs, while others specialize on discrete habitats, which typically have lower connectivity at a landscape scale. For example, the Mojave Desert fringe-toed lizard (*Uma scoparia*) is a dune obligate species, and thus is limited to areas of extensive windblown sand dunes. Mojave fringe-toed lizards are found at Dumont dunes and Kelso dunes on California, and Big Dune in Nevada; and are present at >25 known currently isolated localities (Norris, 1958). While isolated to dunes, this species can be found in areas with Eolian sand substrates throughout the Mojave where drainages transport alluvium into lower areas where sand accumulates (Norris, 1958). There are also Sonoran species of fringed-toed lizards (e.g., the *U. notata* complex), occurring in the Lower Colorado Subdivision of the Sonoran Desert and south of the Mojave desert ecoregion. Recent genetic research indicates a distinct separation of these two related taxa with a Pleistocene origin of *U. scoparia*, without gene flow between them, despite their relative proximity compared to within species distances (Gottscho et al., 2014). Mountains uplifted along the San Andreas Fault during the Miocene are thought to have maintained vicariance between the two taxa, and the Pleistocene origin of *U. scoparia* is considered to be a founder effect, where colonization occurred with a small—one-time dispersal into the Mojave. Within the Mojave there is little genetic structure among populations of *U. scoparia* despite their geographic isolation, which may be due to their recent expansion within the Mojave (Gottscho et al., 2014). Similar patterns are seen in "island like" restricted fish and dune obligate insects in the Mojave, where divergence among populations lacks evidence of being driven by geographic processes, and is better explained with chance founder events (Van Dam and Matzke, 2016). A study of the flora on sand dunes was used to estimate the relative ages of the dunes (Pavlik, 1989). The migration of the dune flora indicate colonization of the dunes emanating from the valleys north of the Mojave (i.e., Mono Basin east of the Sierras, Fish Lake, and Big Smokey Valleys in west Central Nevada) southward along the east and west sides of Death Valley during the late Pleistocene/Early Holocene. Dune formation in Death Valley was later with mid- to late-Holocene dune formation and plant colonization northward into Panamint and Death Valleys (Pavlik, 1989).

Biogeography

The biogeography of the Mojave as we see it today is driven by the history of the topography, and climate, interacting with the flora and fauna of the region. The region has a broad elevational range from −86 m at the bottom of Death Valley, to Mt. Charleston in Clark County NV at 3632 m. Other high elevation ranges serving to create "sky island" habitats include Telescope Peak in the Panamint Range in Death Valley at 3367 m, and Hayford Peak in the Sheep Range in southern Nevada at 3021 m. The Mojave has a low number of endemic species, partially due to the climatic, rather than physical obstacles defining its borders to the north and south (Bell et al., 2010). Until recently only three terrestrial endemics were recognized; the Joshua tree, the Mohave ground squirrel (*Xerospermophilus mohavensis*), and the Mojave fringe-toed lizard (*Uma scoparia*; Bell et al., 2010), although genetic research continues to yield new species. Joshua trees are now recognized as two species (Lenz, 2007), and the Mojave desert tortoise *Gopherus agassizii* was recently recognized as a separate species unique to the Mojave, after being split from the Sonoran Desert Tortoise—*G. morafkai*, which inhabits the Sonoran Desert east of the Colorado River (Murphy et al., 2011). In addition, there are many aquatic species endemic to the Mojave associated with springs, and permanent and ephemeral water systems. For example, endemic fishes, most of which are rare and of conservation concern, include Tui Chub (*Gila* spp.), Dace (*Lepidomeda* spp., *Rhinichthys* spp., *Moapa coriacea*), Pupfish (*Cyprinodon* spp.), Suckers (*Catostomus* spp.), and Springfish (*Crenichthys* spp.), among others (Williams et al., 1985). There are also many endemic aquatic macroinvertebrates in hundreds of isolated spring systems throughout the Mojave where Springsnails (*Pyrgulopsis* spp.) have radiated under recent isolation (Hershler and Liu, 2008) and have become a recent conservation concern due to over apportionment of water resources, and draw down of aquifers (Hershler et al., 2014; Sada et al., 2005).

Speciation in the Mojave is thought to be a result of the recent assembly of many of its current inhabitants during the late Pleistocene, as species emigrated from refugia occupied during glacial advances, and when the region was inundated with pluvial lakes. Indeed, the Mojave flora is an admixture of species from the cooler Great Basin desert to the north, the Colorado Plateau to the northeast, and the warmer and wetter Sonoran desert to the south (Axelrod, 1983; Barbour et al., 2007; Turner, 1994a). Geological events in the Miocene separated species in the region much earlier, as the Sierra and Transverse Ranges experienced uplifting, and eventually caused rain shadows in the valleys to the east (Bell et al., 2010; Vandergast et al., 2013). The Transverse

Ranges rose along the San Gabriel fault 10 – 5 Mya, which stopped the drainage of the Mojave River in the west Mojave from flowing down the Cajon Pass and redirected it toward the interior of the basin toward Coyote Lake near what is now Barstow California. Uplift of the ranges also terminated the Mojave at Silver Lake/Death Valley north of what is now the town of Baker California (Cox et al., 2003). Evidence of that wetter period can be found in the shells of large extirpated bivalve species in the dry lake beds today. The large alluvial fans (bajadas, Bowman, 2019) that comprise much of the Mojave upland habitat resulted from erosion due to increased runoff from major deposits that were formed during the Pleistocene during wetter pluvial periods in the region (Cox et al., 2003). Additional soil deposition events occurred at the Pleistocene/Holocene boundary 9.4–10 kya which may have been due to increased storm cycles (Harvey et al. 1999; McDonald et al., 2003).

In addition to changing the hydric environment, the mountains bordering the western Mojave serve as vicariant boundaries that limit the dispersal of organisms, resulting in relatively distinct flora and fauna on either side of the Transverse Range (Fig. 2, Bell et al., 2010). Incursions of the Salton Trough in southern California during Pleistocene pluvial periods served as boundaries resulting in divergence in many mammal species between the Mojave and Sonoran deserts in California and Arizona (Hafner and Riddle, 2011). The inundation of currently upland habitats occurred when higher sea levels force the Sea of Cortez to surge northward along the Bouse Embayment. The Bouse Embayment is a low elevation geographic area following the Colorado River drainage for approximately 275 km (north of its current merger with the Sea of Cortez) during the late Pliocene some 6 to 5.3 Mya (Lucchitta, 1979, Fig. 2). These events corresponded more closely with species differentiation for nine of 12 species across broad taxonomic groups than did climatic fluctuations corresponding with Pleistocene glacial and pluvial periods (Wood et al., 2013). Only three of the 12 species had evidence of divergence only during the Pleistocene, while most showed evidence of differentiation related to both time periods (Wood et al., 2013). Similar divergence patterns in other species indicate that the Bouse Embayment was likely an important vicariance that led to allopatric/vicariant speciation, separating Mojave and Sonoran species during the Pliocene/Miocene (Hafner and Riddle, 2011). Species which are thought to have been separated in this way include the Mojave desert tortoise (Edwards et al., 2015; Murphy et al., 2011), western spotted skunk–*Spilogale gracilis*, (Ferguson et al., 2017), some species of pocket mice (*Perognathus* spp.) and kangaroo rats (*Dipodomys* spp.; Riddle, 1995). However, this mechanism was not sufficient to explain divergence in species of desert tarantula (*Aphonopelma* spp.)—other mechanisms, such as the inclusion of Miocene tectonics may warrant consideration (Graham et al., 2015).

In a recent study, most species also showed evidence of population expansions 100–200 kya, which is consistent with the re-invasion of species to the Mojave desert lowlands as the climate warmed and dried (Wood et al., 2013). Desert scorpion (Scorpionidae) divergence is also thought to be consistent with a post Pleistocene origin model (Graham et al., 2013). While the Mojave was once dominated by a Piñon/Juniper woodland, the climate fluctuations, and an eventual drying period resulted in a transition to the current creosote/bursage dominated landscape (Vandergast et al., 2013), but not beginning until around 23 kya, with evidence of *Larrea* becoming a dominant species in the Mojave approximately 7 kya (Turner, 1994a; Harvey et al., 1999; Vandergast et al., 2013). Given these relatively recent changes in climate and vegetation it is clear that some desert species may be exapted to desert habitats, such that they arrived in this desert environment with adaptive capacity, rather than evolving specialized adaptations to survive in harsh desert environments in situ, the desert tortoise among them (Morafka and Berry, 2002).

While the divergence mechanisms and the timing of separation are different among species (e.g., Graham et al., 2015), there are clear zones where species have separated and diversified along the boundaries of the Mojave Desert ecoregion. Recent research using a diverse group of species analyzed genetic divergence and diversity, and found strong separation of species along the Mojave/Sonoran boundary both west and east of the Colorado River (Vandergast et al., 2013). That study identified 10 evolutionary hot-spots where up to 17 species demonstrated high levels of genetic divergence within relatively local areas. Thus, while the vegetative boundaries between these adjacent deserts are gradual (Barbour et al., 2007; Turner, 1994a), there are sufficient environmental differences between the Mojave and Colorado (Sonoran) desert regions to yield genetic separation among species (Vandergast et al., 2013).

Species Connectivity

Some species are highly connected across the landscape of the Mojave Desert through the matrix of low elevation bajadas and basins, such as the Mojave desert tortoise, and exhibit a genetic pattern known as ‘isolation by distance’ (Hagerty et al., 2011), where individuals that are close together geographically share more genetic similarities and more recent ancestry than those that are farther apart. Because genetic connectivity is well characterized in the Mojave Desert Tortoise it provides a good illustration of patterns found in other widely distributed bajada/basin species.

Desert tortoise populations exhibit genetic structure that reflects geographic barriers at regional scales, but show low levels of differentiation across broader landscapes in the absence of those barriers, with gradual changes in genetics operating on a large gradient (Hagerty and Tracy, 2010). For example, three basal populations were identified in a north south orientation, where tortoises west of Death Valley, and south of the Ivanpah Valley, CA form a southern “California Cluster.” While tortoises in the Ivanpah, Mesquite, Amargosa and Las Vegas valleys form a “Las Vegas Cluster,” and populations North and East of the Pahranaagat Valley form a “Northern Mojave Cluster.” Each of these major valley systems are bounded by mountainous regions that tortoises do not traverse easily (Hagerty and Tracy, 2010). At a landscape scale, desert tortoise populations are well connected, and genetic distances (i.e., a measurement of differences in genetic composition within or between populations) generally correspond to straight line distances. However, where large geographic barriers (e.g., high and rugged mountain ranges) exist they reduce genetic connectivity around these barriers, and thus funnel connectivity through areas connected by more favorable habitat (Hagerty et al.,

2011). The open habitats of the west Mojave support generally well connected populations with lower pairwise genetic distance values, while comparisons among populations separated by barriers in the east Mojave tend to have higher differentiation (Hagerty et al., 2011). The Mojave Desert Tortoise as separated from its related taxon, the Sonoran Desert Tortoise (*G. morafkai*), 8 – 4 Mya when the Colorado river formed in the late Pliocene. Interestingly, the river channel has meandered broadly through time, apparently creating a pattern of “stepping stone” habitat for the species to cross the channel to Arizona habitat, and resulting in a secondary contact zone between the two species (Edwards et al., 2015). This exchange of individuals resulted in *G. agassizii* individuals becoming isolated on the eastern side of the Colorado River, where they have hybridized with *G. morafkai* near the Hualapai Mountains. The hybrid tortoises exhibit intermediate habitat preferences compared to either the Mojave Desert Tortoise or the Sonoran Desert tortoise. Mojave Desert Tortoise habitats consist largely of lower bajadas and upland slopes and typified by Mojave desertscrub, Mixed Mojave desertscrub or vegetation of the Lower Colorado River Subdivision of the Sonoran Desert; while the Sonoran desert tortoise is more commonly found in higher and rockier upland mountain slopes with higher perennial vegetation density and diversity of the Arizona Upland Subdivision of the Sonoran Desert (Edwards et al., 2015; Nussear and Tuberville, 2014).

Biogeographic Isolation and Landscape Connectivity

Much of the Mojave landscape consists of bajadas and uplands composed of alluvial fans ranging from 600 to 1200 m (Norris, 1958), emanating from a series of mountain ranges with a network of drainages leading to terminal dry lakes (playas). The topography of the west Mojave has far fewer mountains (excepting the Transverse Ranges at its western boundary), creating relatively broad and open landscape. As noted—few of the species of mammals, birds, reptiles or amphibians are unique to the Mojave, as most are found in the adjacent deserts as well (Pianka, 1967; Turner, 1994a). Brown (1971) tested the concepts of island biogeography (MacArthur and Wilson, 1963) on boreal mammals (those found elevations above approximately 2286 m along the montane/piñon/juniper border) of California, Nevada, and Utah, and found that isolated mountaintops functioned as “sky islands,” which exhibit low rates of connectivity relative to distance and island size. While Island-like habitat may exist for many species in the Mojave, it is far more the exception than the rule (indeed Brown only found three species in the Sheep range of Nevada, and one in the Panamint range of California that met his definition; Brown, 1971). Most terrestrial species in the Mojave exhibit higher levels of connectivity as they occupy a vast, interconnected matrix of bajadas and basin habitats.

The Anthropocene

Virtually every location within the Mojave has been influenced by the expansive growth of the human population. Studies of land change in the 11 western US states estimated that 13% of the western United States is covered by anthropogenic features, which are mostly agricultural lands, populated areas, and secondary roads (Leu et al., 2008). While the Mojave is largely not an agricultural area, the ecoregion has succumbed to explosive population growth over the last several decades (U.S. Census Bureau, 2010). For example, the Las Vegas Valley in Nevada is home to the largest metropolitan area in the Mojave, and has expanded from 16,414 people in 1940 to an estimated 2.2 million people today (U.S. Census Bureau, 2019). Urban areas, and their associated infrastructure across the landscape, are typically built near the valley floor (Leu et al., 2008); therefore primary and secondary roadways, utility transmission right-of-ways (gas, and electrical), pipelines, and railways traverse nearly every valley in the Mojave with their accompanying infrastructure and human encroachment. Most recently, burgeoning utility scale solar and wind generation facilities have increased habitat losses and fragmentation (Averill-Murray et al., 2012, 2013; BLM, 2016; Inman et al., 2013).

Human infrastructure is not the only anthropogenic influence important to desert species. The Mojave has more than a 100-year history of cattle and sheep grazing. Grazing has led to vegetative change, and changes to soil nutrients and structure (Morafka, 1982). Grazing has also led to the introduction of non-native plant species, which tend to establish in disturbed soils (Beatley, 1966). Red brome (*Bromus rubens* [*madritensis*]) is an especially aggressive Mediterranean grass thought to have been introduced as a result of livestock and crops imported to California during the Gold Rush in the late 1800s (Salo, 2005). The earliest records of red brome near the Mojave region are an arrival in Los Angeles as early as 1887, with records in the Las Vegas area by 1920, and widespread presence throughout the desert by 1960 (Salo, 2005). *Bromus* promotes wildfire spread by providing a fine, continuous, light, and therefore, fast burning fuel in the interstices between native shrubs (Beatley, 1966; Hereford et al., 2006). In recent decades the increased presence of *Bromus*, along with El Niño Southern Oscillation (ENSO) driven increases in winter precipitation (Hereford et al., 2006) have introduced a new threat to the Mojave in the form of wide-spread wildland fires, which have been increasing in size and frequency (Brooks and Esque, 2002; Brooks and Matchett, 2006). For example, in 2005 more than 300,000 acres of Mojave habitat was burned by wildfires, including 36,000 acres of critical habitat for the Desert tortoise (Nussear and Tuberville, 2014; Van Linn et al., 2013). Due to historically low fuel loads provided by predominant environmental conditions in Mojave shrublands, there was not a regular fire cycles in the desert, thus Mojave species are frequently not well adapted to survive wildfire (DeFalco et al., 2010; Esque et al., 2003; Van Linn et al., 2013). The removal of native perennial shrubs eliminates cover for animals and plants from the intense desert insolation and promotes further invasion of *Bromus* and other invasives, which can out-compete native annual species that provide forage for many desert animals (Beatley, 1966; Esque et al., 2014; Nussear and Tuberville, 2014). This can result in a grass/fire cycle that perpetuates this vegetative change resulting in a vegetative state change

(from shrubland to invasive/exotic annual grassland), promoting near monocultures of *Bromus*. The positive feedback loop has been termed a grass/fire cycle (D'Antonio and Vitousek, 1992; Van Linn et al., 2013).

Bromus can also have detrimental nutritional effects (Esque et al., 2014). For example, *Bromus* may impart increased susceptibility to disease, as it has a lower digestive efficiency relative to other potential forage species for desert tortoises, resulting in reduced nutritive value, and increased potential of a reduced immunocompetence (Tracy et al., 2005). There is also the potential for mechanical injury, as the sharp awns on *Bromus* seed can become impacted in the jaws of tortoises (Medica and Eckert, 2007) or damage the gastrointestinal—tracts (Drake et al., 2016; Esque et al., 2014). Together these combined impacts can result in reduction of health condition, growth rates, and survivorship, especially in juvenile animals, and ultimately may reduce population persistence and resilience (Drake et al., 2016) for this, and other native species.

Collectively, this incursion of the human footprint into wide expanses of habitat leads to expansive fragmentation and degradation (Nussenaar and Tuberville, 2014), which can not only influence many taxa, but can also lead to large-scale habitat alterations that change the vegetation composition and habitability of entire landscapes.

Conclusions

The Mojave is a vast area, rich in biodiversity. Its geological and climatic history have led to a diversity of habitats and radiation of species throughout the region. In the last 100 years, there has been an influx of people and associated disturbance in the forms of urbanization and associated infrastructure, habitat conversion to agriculture, and wide-ranging use of the desert for ranching and recreation. These multiple uses have brought with them habitat destruction, degradation, and fragmentation of the landscape that impact many desert dwelling species. Despite the resilience of many of its species, the Mojave desert ecosystem is fragile in nature, and can take centuries for soils and vegetation to recover from disturbance (Webb et al., 2009). While there are many conservation efforts focusing on restoration of desert habitats, they are no substitute for careful planning and management of this fragile ecosystem.

Acknowledgments

Our love and knowledge of the Mojave has been inspired and shaped by our mentors R. Bruce Bury, Philip A. Medica, and C. Richard Tracy. We thank them for instilling our curiosity about this vast desert, which has led to careers of exploring its inhabitants. KEN is supported in part by the National Fish and Wildlife Foundation (NFWF), and the Strategic Environmental Research and Development Program (SERDP), and the Clark County Desert Conservation program (CCDCP). TCE is supported by the USGS Energy Resources, Invasive Species, Wildlife programs.

Abstract

The Sonoran Desert has been identified as one of the most distinctive ecoregions in the world, recognized for its columnar cacti such as the saguaro and cardón. It is home to 130 mammal, 400+ bird, 100 endemic reptile, 750 bee, and nearly 2500 endemic plant species. This great variety of species and habitats is due to the desert's subtropical climate, wide-ranging topography, bimodal rainfall pattern, and location at the crossroads of several different ecoregions. Geologic processes shaped the landscape and created the Gulf of California, a biologically rich body of water that influences the region's climate. The desert's biota faces numerous challenges including increasing temperatures and changing rainfall patterns, loss of native vegetation from invasive species and livestock grazing, habitat fragmentation from transportation and border wall infrastructure, and loss of habitat and riparian areas due to human expansion and groundwater pumping. In the US, nearly 3.88 million hectares (9.58 million acres) is protected from development or other incursions, although other threats to the ecoregion are ongoing. In Mexico, nearly 1.5 million hectares (3.7 million acres) have been set aside as biosphere reserves and other protected areas. A large marine biosphere reserve in the northern Gulf of California has been unsuccessful at preventing the alarming population decline of the vaquita porpoise, which hovers on the brink of extinction.

A Unique Ecoregion

Spanning over 224,000 km² across two countries and four Mexican and US states, the Sonoran Desert encompasses a great variety of species and habitats. The area has been identified as one of the most distinctive ecoregions in the world based on analyses of species richness, species endemism, and global rarity of major habitat types (Olson and Dinerstein, 2002). The species list includes 130 mammals, 400+ birds, 100 endemic reptiles, 750 bees, and over 4000 plants, nearly 2500 of which are endemic to the Sonoran Desert (Nabhan, 2015a). This great biodiversity is due to the subtropical climate, varied geology, wide-ranging topography, and most importantly, rainfall that occurs in both the summer and winter, which supports a broad array of both warm and cool season flora. In fact, this desert has the greatest diversity of plant growth forms, or adaptive strategies evolved to survive high temperatures and drought, of any desert in the world (Nabhan, 2015b).

Geologic History

The contemporary desert Southwest landscape was formed by two main geological events that occurred over millions of years and involved the movement of tectonic plates. The first event occurred from approximately 200 to 50 million years ago, when the Farallon plate was subducted beneath the lighter North American Plate. This action compressed the North American plate, like pushing a rug up against a wall, forming the Rocky Mountains and the Sierra Madre Occidental, and causing much of the volcanic activity in the region.

The second event, starting at about 35 million years ago, occurred as the spreading center between the Pacific plate and the Farallon plate was also subducted beneath the North American plate. Because the Pacific plate was moving in a generally westerly direction, it pulled and stretched this portion of the North American plate along with it. This stretching caused the earth's crust to crack like the surface of a cooling pumpkin pie and formed huge valleys as sections dropped downward in what is called block faulting. The high ground between the valleys remains as today's mountain ranges, creating what is known as the Basin and Range province and the hundreds of isolated mountain ranges that extend from southern Oregon to central Mexico. At about 5.5 million years ago, this motion began pulling the Baja California peninsula away from the mainland of Mexico, eventually creating the Gulf of California. This motion continues today as the peninsula and areas in California west of the San Andreas fault continue moving northwest at a rate of about 5 cm a year (Scarborough and Brusca, 2015).

Defining the Ecoregion

The Sonoran Desert (Fig. 1) is at the crossroads of several different ecoregions and biotic communities that contribute to its incredible biodiversity. To the north, interior chaparral leads to the higher-elevation montane conifer forests of the Mogollon Rim. The west and east edges are bookended by the peninsular ranges of southern California and the grasslands and woodlands of the Sky Islands. Sinaloan thornscrub, the ancestral biome from which many Sonoran Desert plants and animals evolved, transitions into tropical deciduous forests further south (Van Devender and Brusca, 2015).

The Sonoran Desert is visually distinguished from other North American deserts by two life forms: legume trees such as the acacia, and large columnar cacti (Dimmitt, 2015). These cacti include the saguaro (*Carnegiea gigantea*) and the cardón (*Pachycereus pringlei*), the largest cactus in the world. Forrest Shreve first described and mapped the boundary of the desert in 1942 while working at the Carnegie Institution's Desert Laboratory in Tucson (Shreve, 1942). Being a botanist, he differentiated the deserts based on their floristic composition, physical appearance, and community structure of the dominant plant species. He subsequently refined his description of the Sonoran Desert and defined seven subregions that included the deserts of the Baja California peninsula (Shreve, 1951).

More recently, scientists have used a different approach to define the boundaries of the Sonoran Desert (Riddle et al., 2000). They used DNA to reconstruct the historic processes that are responsible for the contemporary geographic distribution of species in the desert. They found that the desert biota of the Baja California peninsula has a unique evolutionary history, as distinct as the other regional deserts, and proposed that it should be considered a separate desert, the Peninsular Desert, instead of a subdivision of the Sonoran Desert. This additional classification has not been met with wide acceptance (Hafner and Riddle, 2011), but for the purposes of this chapter we will discuss the Sonoran Desert and Baja Peninsular Desert as separate entities.

Vegetative Subdivisions of the Sonoran Desert

Desert plants are supremely adapted to their arid environment. To people from wetter parts of the planet, it may appear that they are just eking out an existence, but in fact, these plants could not survive in wetter places. They thrive in the desert. Their adaptations to aridity include succulence (the ability to store water in fleshy leaves, stems, and roots), extensive shallow root systems designed to absorb water from any rainfall, waxy coatings to prevent water loss from stems and leaves, small leaves to prevent overheating and limit water loss, and green stems which provide photosynthesis even when leaves are small or absent. Another strategy is drought-avoidance, as displayed by annual plants which complete their life cycles during brief wet seasons and then die after channeling all their energy into producing seeds (Dimmitt, 2015).

Lower Colorado River Valley

The largest, hottest and driest subdivision is found along the Lower Colorado River, and is second only to the Mohave Desert's Death Valley as the hottest and driest place in North America. Summer highs can exceed 120 F (48.5C), and humidity is often less than 10%. Annual rainfall in the driest areas is generally less than 75 mm, and it is not uncommon for some locations to go two or 3 years without rain. Even so, life exists here, and is abundant in the rare wet years (Dimmitt, 2015).

The landscape in this subdivision is dominated by broad flat basins interrupted by small rocky ranges. It includes the Gran Desierto de Altar, a 5700 km² sand sea, the only area one might recognize as stereotypical desert. The spectacular Pinacate volcanic field lies within this sub-region as well. The valleys are dominated by low shrubs, primarily creosote bush (*Larrea tridentata*) and white bursage (*Ambrosia dumosa*). These are the two most drought-tolerant plants in North America, but in the driest areas of

Fig. 1 Map of the Sonoran Desert and surrounding ecoregions by Curtis Bradley. Data Source: Ecoregions 2017 © Resolve.

this subdivision even they are restricted to drainages. Trees are found only in the larger washes. The mountains support a wider variety of shrubs and cacti, but the density is sparse. Columnar cacti are rare and restricted to drainages. Annual plants comprise well over half the flora (90% at the driest sites), and are abundant only in wet years (Dimmitt, 2015).

Arizona Upland

This northeastern section, mostly in south-central Arizona and northern Sonora, is the highest and coldest subdivision of the Sonoran Desert (Fig. 2). The terrain contains numerous mountain ranges, and the valleys are narrower than in the Lower Colorado River Valley subdivision. Trees are common on rocky slopes as well as drainages, and saguaros are found everywhere except the valley floors. This community is also called the saguaro-palo verde forest. It is the only subdivision that experiences frequent hard winter frosts, so many species of the lower elevation and more southerly subdivisions cannot survive here.

The Arizona Upland is home to a great variety of cacti, ranging from saguaros that can reach heights of 12 m to several tiny species less than 10 cm. There are tall columnar cacti, round cacti (barrels), jointed stick-like cacti (chollas), and cacti with flat

Fig. 2 Arizona Upland in the Tucson Mountains. Photo by Dug Schoellkopf.

pads (prickly pears). Other common plants found here are agaves (*Agave spp.*), yuccas (*Yucca spp.*), and legumes such as mesquite (*Prosopis spp.*), palo verde (*Parkinsonia spp.*), ironwood (*Olneya tesota*), and acacia (*Acacia spp.*). Low shrubs include white bursage, brittlebush (*Encelia farinosa*), jojoba (*Simmondsia chinensis*), ocotillos (*Fouquieria splendens*), and a variety of desert grasses.

Central Gulf Coast

The Central Gulf Coast subdivision occupies strips along both sides of the Gulf of California, and desert vegetation grows right to the seashore. Small shrubs are nearly absent; their shallow root systems and lack of water storage cannot sustain them through the extreme aridity here. Dominating the vegetation are large stem-succulents, particularly the massive cardón (**Fig. 3**) and trees such as palo verde, ocotillo, ironwood, elephant trees (*Bursera spp.*), and limberbush (*Jatropha spp.*), which are leafless most of the time. The average annual rainfall of less than 5 in (125 mm) occurs mostly in summer, though not dependably enough to call it a rainy season ([Dimmitt, 2015](#)).

Plains of Sonora

The Plains of Sonora, a small region of central Sonora, is similar to the Arizona Upland with denser vegetation (due to more rain and deeper, finer soils) and additional tropical species. Most of the subdivision has been converted to agriculture ([Dimmitt, 2015](#)).

Climate

Annual precipitation in the Sonoran Desert ranges from 50 to 400 mm (2–16") a year with substantial inter- and intra-annual variability in timing and quantity. Lower elevations near the Colorado River and Gulf of California receive the least amount of rain and higher elevations near the Sierra Madre Occidental receive the most. The desert is situated at 28–34° latitude which, combined with its location at the western edge of a large land mass, is in an area dominated by sinking, dry equatorial air and high pressure that serves to reroute incoming frontal storms. During the cooler winter months, from December to March, this high pressure breaks down and moisture from the Pacific Ocean arrives on the back of strong westerly winds. Much of this moisture is lost on the windward side of the peninsular mountain ranges of Southern California and Baja California, and never makes it to the desert. This rain shadow effect is caused when an air mass is forced up and over a mountain range, cooling it, and thus causing the moisture to precipitate out as rain or snow.

There are five seasons in the Sonoran Desert: fall, winter, spring, and two summer seasons. Fore-summer occurs in May and June and is characterized by cloudless, dry, sunny days with temperatures commonly exceeding 40 °C (104 °F). Monsoon season typically arrives in early July and is characterized by a shift in the wind patterns, increasing humidity, and chances for rain. The North American monsoon shares the basic characteristics of the Indian counterpart but lacks its duration and intensity. The event is created by several factors working in concert. A thermal low-pressure system forms near the Arizona and California border created by rising air from the intense solar heating of the Earth's surface. This pulls in low level moisture from the nearby warm waters of the Gulf of California. Secondly, a high pressure system develops over the Four Corners area where the US states of Arizona, New Mexico,

Fig. 3 Organ pipe cactus (*Stenocereus thurberi*) in foreground, cardón, and saguaro in background. Photo by Sky Jacobs.

Colorado, and Utah meet. The air cools over this higher elevation area, falling, and creating a counter clockwise air flow that draws in higher-level moisture from the Gulf of Mexico. These conditions can combine to produce intense but localized afternoon thunderstorms.

Representative Sonoran Desert Animals

Arthropods

Just as elsewhere in the world, arthropods comprise over 85% of the described animal species in the Sonoran Desert. They are the most important pollinators, and they aerate the soil, and decompose dead plants and animals. Arthropods are also some of the most important herbivores and prey in terrestrial food webs. The Sonoran Desert is a biodiversity hotspot for arthropods. Their great variety of adaptations to desert life, interesting behaviors, and critical ecological functions are fascinating. Each summer during monsoon season, two-legged entomologists swarm the region to study its six- and eight- legged residents.

The most famous/infamous arthropods in the Sonoran Desert are probably its black widow spiders (*Latrodectus hesperus*), tarantulas (*Aphonopelma* spp., **Fig. 4**), and scorpions. Most spiders are venomous, but only the black widow and brown recluse (*Loxosceles* spp.) have venom dangerous to people. The female black widow will sometimes eat the male after mating, thus the name “widow,” although this behavior is actually seen in many types of spiders. Tarantulas are 3 to 4 in. long and commonly seen during the summer rainy season when males leave their burrows to seek out females. They have an unusual defense mechanism: irritating barbed hairs that they can brush onto the mouth, nose or paws of a predator.

There are more than 30 species of scorpion in the region. They occur in a great variety of habitats, spending much of their time underground, under rocks or, as with bark scorpions, high above ground in trees or in rock crevices. Scorpions give birth to live young which quickly clamber on to their mother’s back to hitch a ride until their first molt. One of the most unusual traits of scorpions is that they fluoresce under ultraviolet light ([Lizotte, 2015](#)).

Many other arthropods are keystone ecological players in the Sonoran Desert. The region is home to more than 750 species of bees. They range in size from the world’s smallest bee, *Perdita minima*, measuring less than 2 mm, to carpenter bees (*Xylocopa* spp.),

Fig. 4 Arizona-Sonora Desert Museum. Photograph of tarantula by Howard Byrne III.

which are up to 40 mm long. Unlike most other groups of animals, bee diversity peaks in deserts and savannahs, rather than in rainforests. Most native Sonoran Desert bees are solitary, creating nests inside perfectly circular holes dug in the ground, although some make their nesting holes in dried stems or wood (Buchmann, 2015).

Birds

People flock from all over the world to catch a glimpse of both the diversity and distinctiveness of the Sonoran Desert's more than 400 bird species (Fig. 5). Some of the greatest stars are the dozen or so hummingbird species that live in or pass through the region. They include the smallest birds in the world and range from 7 to 13 cm. They have the most brilliant iridescent colors, the fastest wingbeats, and the most amazing flying acrobatics, with the ability to fly up, down, sideways, and backward.

Fig. 5 The cactus ferruginous pygmy-owl (*Glaucidium brasilianum*) was formerly common in the Arizona Upland subdivision but is now considered endangered in the United States due to habitat loss. Photograph by Sky Jacobs.

The greater roadrunner (*Geococcyx californianus*) is probably the most iconic desert bird. These birds can fly, but usually walk or run instead. In the open, they can reach speeds of 30 km per hour. A fierce predator, the roadrunner can catch snakes, lizards, rodents, small birds and insects. They prefer the open habitat of desert or pinyon/juniper.

Gambel's quail (*Callipepla gambelii*) are some of the most visible and audible birds in the Sonoran Desert. They spend most of their time on the ground and are commonly seen scurrying in groups from the cover of one sprawling mesquite to another. During spring and summer, one often sees young quail following their parents in a single file line of 10 or more brown fluff balls. They are common in desert scrub, thorn scrub and riparian areas (Kaufman, 2015).

Of the many hawks and eagles that inhabit the Sonoran Desert, Harris's hawks (*Parabuteo unicinctus*) are the only ones that live and hunt in social groups. They cooperate in defending their nest, and in flushing out prey during a hunt. Other common hawks are Cooper's hawks (*Accipiter cooperii*) and red-tailed hawks (*Buteo jamaicensis*). The American kestrel (*Falco sparverius*) is a familiar sight as well. This small falcon can reach great speeds chasing the large insects that make up most of its diet. Another bird in the falcon family, the crested caracara (*Caracara cheriway*), is a large, majestic, slow-flying bird that will catch live prey or eat carrion. It is mainly a tropical bird, common in the southern part of the Sonoran Desert, however its range is expanding northward into Arizona (Jennes, 2015). Many other birds inhabit the diverse landscape and soundscape of the Sonoran Desert, much too numerous to list here.

Mammals

Over 40 species of bat live in the Sonoran Desert Region. Bats are one of the most diverse groups of mammals and one of the most threatened. White nose syndrome, which has devastated bat populations in the northeast US, has not yet reached the Sonoran Desert. Bats keep insect populations in check and are important pollinators of many Sonoran Desert plants, including the iconic columnar cacti (Tyburec, 2015).

Sonoran Desert canids include coyotes (*Canis latrans*), gray fox (*Urocyon cinereoargenteus*), and kit fox (*Vulpes macrotis*). Coyotes are found in all habitats, while gray foxes prefer rocky canyons and kit foxes like more open flats, with deeper soils for digging their dens. Coyotes appear prominently in the stories people have told about this region throughout time. All three desert dogs are omnivores, eating whatever they can find. Coyotes are mostly social animals, living in small family groups and filling the desert with their yips and howls whenever there is news to share, but especially at dusk. Gray foxes can climb, forage and sleep in trees, safe from many of their predators. Kit foxes are nocturnal and use their underground dens year-round. They can survive without free water, getting all the water they need from their food. The endangered Mexican gray wolf (*Canis lupus baileyi*) also lives in the region, in the mountains at the desert's edges.

Four wild cats make their homes in the Sonoran Desert region. The largest two, the jaguar (*Felis onca*) and mountain lion (*Felis concolor*), live mostly in the sky islands. Bobcats (*Felis rufus*) are common in many habitats, including people's back yards. Ocelots (*Felis pardalis*) are found in thorn scrub, oak woodland and riparian areas in Sonora, Mexico, and are rarely seen in the northern part of the Sonoran Desert.

Two distinctive, but rarely seen Sonoran Desert mammals are the ringtail (*Bassariscus astutus*; Fig. 6) and coati (*Nasua narica*). Both are related to raccoons in the procyonid family. Ringtails are squirrel-sized, with large eyes and a long fluffy ringed tail. They have excellent climbing abilities and are solitary and nocturnal. Coatis are social animals, living in large bands of up to 30 individuals in riparian areas or oak-sycamore canyons. They are longer and thinner than a raccoon with a longer snout ringed tails. They often walk with their tails erect. Both of these animals, like raccoons, are omnivores.

Other Sonoran Desert mammals are: desert bighorn sheep (*Ovis canadensis nelsoni*), Sonoran pronghorn (*Antilocapra americana sonoriensis*) and multiple species of skunks, badgers, deer, rabbits, and a variety of rodents, many with fascinating adaptations to the heat and aridity of the desert.

Fishes and Amphibians

"Desert fish" may sound an oxymoron, but fish are also found in the Sonoran Desert. Many washes that are dry today were once streams that ran at least intermittently. There are dozens of freshwater species native to the region, and even more that have been introduced. Native species include the small (5 cm) Gila topminnow (*Poeciliopsis occidentalis*) and the largest minnow in the region—the 1.8 m Colorado pikeminnow (*Ptychocheilus lucius*). At least two thirds of the native species are threatened or endangered due to loss of habitat and competition from nonnative species (Ivanyi and Marsh, 2015) including the Sonoyta or Quitobaquito pupfish (*Cyprinodon eremus*), which is found in one location on the Rio Sonoyta in Sonoran and at Quitobaquito Springs in Organ Pipe National Monument.

Sonoran Desert amphibians have evolved some ingenious methods to get and keep the water they need. For example, Couch's spadefoots (*Scaphiopus couchii*) burrow into moist soil and emerge to feed and breed only on rainy nights. They lay their eggs in temporary ponds, and they hatch and metamorphose in less than 2 weeks, hopefully before the pond has dried up. Similarly, the large (18 cm) Sonoran Desert toad (*Incilius alvarius*) spends most of the year in rodent or other underground burrows, emerging in the rainy season to mate and feed. Their tadpoles take longer to mature – 6 to 10 weeks, requiring larger or longer-lived ponds to complete the life cycle. Both types of amphibian are generally nocturnal (Ivanyi et al., 2015).

Fig. 6 Ringtail Photo by Paul and Joyce Berquist.

Reptiles

Sonoran Desert tortoises (*Gopherus morafkai*) are widespread throughout the region. They survive the heat of summer days and the cold of winter in a hibernation-like state in burrows, which they dig with strong, flattened, front legs. They extract water from the plants they eat and will drink free water if it's available. Their bladder has the capacity to store 40% of their body weight in water to get them through long dry spells. Gila monsters (*Heloderma suspectum*, **Fig. 7**) are one of only two medically significant venomous

Fig. 7 Gila monster. Photograph by Alex Kerstitch.

lizards in the world, the other being the beaded lizard found along the Pacific slopes of Mexico from Southern Sonora into Guatemala. The Gila monster is a large wide-bodied lizard, reaching about 45 cm in length and brightly bedecked in bands or a network of pink, red, or orange, contrasted with black—which is considered warning (aposematic) coloration (Ivanyi et al., 2015).

There is a great diversity of other lizards and snakes in the Sonoran Desert, reflecting not only the diversity of habitats, but the region's position adjacent to grasslands of the mid-continent and the tropics to the south. A species that is adapted to the Sonoran Desert is the Tucson shovel-nosed snake (*Chionactis annulata klauberi*), a non-venomous mimic of the Sonoran coral snake (Fig. 8). It has a specially adapted spade like snout that allows it to burrow or “swim” through sandy soils and preys on everything from beetle larvae to scorpions.

Arizona is home to at least 18 different varieties of rattlesnake and, if you add in those found in the state of Sonora and the Baja California peninsula, as well as species found on islands in the Gulf of California, this region easily rivals any other in rattlesnake diversity. Rattlesnake venom is a highly specialized mixture of enzymes that attacks blood, tissue, heart and nerves. They are most active in the warmer seasons, and mostly nocturnal in the summer. To aid seeing in the dark, they have a pair of unusual infrared-sensing organs that help them find prey, avoid predators, and navigate the challenging thermal landscape in which they live (Ivanyi et al., 2015).

Indigenous Peoples and Colonization

Humans have been living in Sonoran Desert for at least 13,000 years, shaping its ecosystems and biodiversity, just as the environment has shaped human cultures through time. Some scientists believe that Paleo-Indians contributed to the extinction of large megafauna that roamed North America during the Ice Age. Archeologists have documented changes in the abundance of various mammal species near early human settlements due to human consumption patterns. Hohokam people built extensive irrigation networks and cleared desert vegetation for fields and firewood. The Seri people on the Sonoran coast helped to expand the range of several species of reptiles during their travels. For at least 4000 years, Sonoran Desert peoples such as the O’odham, Cocopas, Yoemem, and Mayos (and their ancestral cultures) cultivated maize, tepary and pinto beans, gourds, squash, cotton, amaranth, devil’s claw, agaves, and many other plants, changing their abundance and distribution on the landscape (Sheridan, 2015).

With the arrival of Europeans in the 16th century, came the devastating dispersal of new diseases, which are estimated to have killed up to 95% of the indigenous population. Europeans also brought new plants and animals including winter wheat, fruit trees, mules, oxen, cattle, sheep, goats, and horses, which further changed the landscape and biodiversity. The discovery of silver and gold deposits in the late 17th century accelerated this trend. Ranching and mining settlements were developed. The railroad arrived in the 1880s, followed by cattle, copper, and cotton. Each did their part to remake portions of the Sonoran Desert. The widespread availability of air conditioners starting in the 1940s led to rapid urban growth in Arizona. Each successive wave of human settlement left its mark on the biome we call the Sonoran Desert, a process that continues today (Sheridan, 2015).

Fig. 8 The venomous Sonoran coral snake (*Micruroides euryxanthus*) is distinguished from its non-venomous shovel-nosed mimics by its black snout and thicker bands. Photograph by Sky Jacobs.

Threats to Biodiversity

Climate Change

Nearly all the world's biomes have experienced temperature increases over the last 50 years, and the Sonoran Desert is no exception. According to the Fourth National Climate Change assessment, the region has already seen a 0.89 °C (1.61 °F) increase in average annual temperature since the beginning of the 20th century. This is predicted to increase by an additional 2.7 to 4.8 °C (4.9–8.7 °F) by the end of this century under the lower (RCP4.5) and higher (RCP8.5) emissions scenarios, respectively (Wuebbles et al., 2017).

Changes in rainfall patterns have been equally significant (Fig. 9). Regions of the Sonoran Desert have experienced a 15% reduction in precipitation (USGCRP 2017), and a 19% reduction of flows has been observed on the Colorado River (Udall and Overpeck, 2017). Most models forecast less winter and spring rain and lower overall precipitation in the future. At the same time, rainfall intensity, or the amount of rain in a given period of time, is predicted to increase during summer thunderstorms because warmer air can hold more moisture. Summer rains typically produce localized precipitation that does not percolate into the soil as deeply as winter rains that originate from large Pacific Ocean frontal systems (MacMahon and Wagner, 1985).

These changes in climate are predicted to affect the distribution and abundance of many Sonoran Desert species. The hotter temperatures will mean a decrease in available soil moisture due to increased evapotranspiration. Plants with root systems that can tolerate water stress and can utilize summer versus winter precipitation will be favored. This change is being observed with the reduction of foothill paloverde (*Parkinsonia microphyllum*) and ocotillo (*Fouquieria splendens*) on south and west facing slopes (Munson et al., 2011). It is also predicted that many of the desert's plant species ranges will move up in elevation in response to climate change. A study on the Santa Catalina Mountains near Tucson found that 15 of 27 plant species already had shifted higher in elevation over a 49-year period (Brusca et al., 2013).

Invasive Species

An invasive species is defined by the U.S. Department of Agriculture as a species that is non-native to that ecosystem and whose introduction will cause economic or environmental harm. There are several invasive plants that pose a threat to the native plants of the Sonoran Desert either through competition or by changing the fire regime. Fast growing annuals such as red brome (*Bromus*

Fig. 9 Projected change (%) in total seasonal precipitation from CMIP5 simulations for 2070–99 relative to the 1976–2005 average. These are results for the higher scenario (RCP8.5). Stippling indicates large changes and hatching indicates small changes as compared to natural variations. Data source: World Climate Research Program's (WCRP's) Coupled Model Intercomparison Project. Figure source: NOAA NCEI - National Oceanic and Atmospheric Administration National Center for Environmental Information.

rubens), Arabian grass (*Schismus arabicus*), Sahara mustard (*Brassica tournefortii*), and cheatgrass (*Bromus tectorum*) outcompete native annuals. Perennials such as buffelgrass (*Pennisetum ciliare*), and fountain grass (*Pennisetum setaceum*) can grow large and dense enough to compete with native shrubs for light and nutrients (Dimmit and Fusari, 2015). Saltcedar (*Tamarix* spp.) is an invasive tree that displaces native trees in riparian areas that are habitat for many birds.

Buffelgrass, native to the savannas of Africa and India, has been planted in Sonora and Arizona since the 1950s to increase forage for cattle production (Brenner, 2011). In Sonora, buffelgrass cultivation boomed from government-subsidized programs to support the ranching industry. By 2002, nearly 1.6 million hectares of land in Sonora had been cleared and seeded with buffelgrass (Búrquez et al., 2002). In Arizona, its planting was promoted by the US department of Agriculture as a soil stabilizer and is now a common sight in disturbed areas, along roads, or in desert scrub covered slopes. It produces large amounts of seed in response to rain but its ability to withstand fire is what makes it a threat to the desert.

Native vegetation is not dense enough to support fires larger than a few hectares and plants such as the giant saguaro have not evolved with fire. Whereas a single fire can kill significant numbers of cacti and succulents, buffelgrass will quickly colonize these disturbed areas, repeat the fire cycle, and expand to form dense, single species stands. Once buffelgrass is established in an area it is extremely difficult to eradicate (Fig. 10).

Livestock Grazing

Domestic cattle are another invasive species that arrived in 1540 with the Spanish explorer Coronado and were subsequently promoted by the numerous missions in the region (Fleischner, 2010). By the late nineteenth century, large numbers of livestock roamed the Southwest and their overgrazing, combined with a severe drought, converted the majority of the desert grasslands into desert-like scrublands that persist today (Dimmit and Fusari, 2015) (Fig. 11). Livestock grazing is now permitted on 3.6 million hectares of the Sonoran Desert ecoregion and across 1 million square kilometers of public lands in the United States. Grazing has a far greater impact on ecosystem health than do all roads, timber harvest, and wildfires combined (Beschta et al., 2013).

Soil compaction from livestock grazing has severe effects on deserts soils and has been identified as an extensive problem on US public lands (FS and BLM, 1997). This is because the weight of a 450-kg cow will exert more than five times the compacting pressure of a bulldozer and significantly reduce the soil's ability to store water (Cowley, 2002). When the soil cannot store as much water due to compaction and reduction of plant cover due to overgrazing, increased runoff will occur during high-intensity rainfall events of the summer monsoons (Branson et al., 1981). The increased runoff causes erosion, loss of topsoil and the downcutting of stream-banks and washes commonly seen in western landscapes.

Fig. 10 Buffelgrass and saguaros on Tumamoc Hill in Tucson, Arizona. Photo by Curtis Bradley.

Fig. 11 Soil loss from cattle grazing in a mesquite bosque that once supported sacaton grass. Photo by Sky Jacobs.

Border Wall

Since the early 1990s, the U.S. government's border control efforts have been driven by a "prevention through deterrence" strategy—the concept that increased personnel and infrastructure will discourage undocumented immigration. This strategy was first implemented in heavily populated border areas such as San Diego and El Paso and shifted immigration, drug trafficking and other activities to more remote areas of the Sonoran Desert, causing extensive environmental damage and social disruption.

Border wall construction accelerated with the passage of the 2006 Secure Fence Act, which mandated more than 1287 km (800 miles) of border wall construction, and the REAL ID Act of 2005, which gave the secretary of Homeland Security the power to waive US environmental laws to expedite construction (**Fig. 12**). In total, Homeland Security has installed 570 km (354 miles) of primary border wall ("pedestrian fencing") as well as 482 km (300 miles) of vehicle fencing ([United States, 2017](#)).

Fig. 12 Border pedestrian fencing along Organ Pipe National Monument. Photo by National Park Service.

Border walls threaten the biological integrity of the borderlands through direct habitat destruction, fragmentation, and creation of barriers between wildlife populations. These barriers prevent essential movement and gene flow while facilitating increased vehicular traffic and human disturbance in previously undisturbed areas (ACE, 2001).

One of the species that would be affected by additional proposed border wall infrastructure is the Sonoran pronghorn, whose population has declined to fewer than 1000 animals. Pronghorn require immense open areas and must travel long distances in search of food and water. They are also particularly sensitive to disturbance from human activities. The proposed border wall would limit their ability to travel freely in search of food and water and would permanently separate the species' northern and southern populations, preventing dispersal and gene flow that are essential to their survival and recovery.

Several scientific studies demonstrate the impact the wall is having on animals of the Sonoran Desert. Flesch et al. (2010) examined two species, the cactus ferruginous pygmy owl and desert bighorn sheep, and found that these species along with others with similar movement abilities and spatial distributions may be affected by border development. McCallum et al. (2014) used camera traps to compare movements of people and wildlife between areas with and without border walls and found that both pumas and coatis were recorded in higher numbers in areas without walls. The authors found no difference in number of people detected between the two, suggesting that intermittent fencing in this area was not effective at deterring human migrants, but did affect wildlife populations.

Land Conversion and Loss of Riparian Habitat

Historically, the southwest deserts of North America were less populated, and less disturbed, than the rest of the continent due to the lack of water and extreme heat. This changed in the mid-20th century with the construction of large-scale irrigation projects bringing water from the Colorado River and the introduction of air conditioning. Since then cities and agricultural lands have grown rapidly and, as of 2014, over 2.9 million hectares (7.16 million acres) of Sonoran Desert in the United States had been converted to urban environments, agriculture, roads, or non-native scrublands.

Damming, diversion of rivers, and ground water pumping to satisfy the booming population have strongly altered riparian areas in the Sonoran Desert and much of the riparian forests have been lost due to changes in land usage (Zaimes, 2007). Persistent drought through the early 2000s has further dried riparian habitats, and climate change models predict continued drying. Riparian areas support more diverse plant and animal communities than the surrounding drier uplands. The impacts of disappearing rivers are most severe for aquatic species—fish, amphibians and some reptiles and arthropods, but many other animals rely on these waters for some part of their life cycle, or for a source of drinking water. Even intermittent streams support denser ribbons of vegetation through the desert, providing more diverse habitat for animals.

Conservation Status and Planning (Fig. 13)

Mexico

Land tenure in Mexico radically changed after the Mexican Revolution and with the land reforms of the Cárdenas presidency of 1934–40. The land reforms redistributed nearly 18 million hectares of expropriated private land into ejidos, or common property used for agriculture (Stoleson et al., 2005). In Sonora, most of the desert ejidos were barely able to produce a subsistence crop and were used for cattle grazing, where it is now the default land use. A 1992 amendment to the Mexican Constitution allowed these lands to be sold and has accelerated the pace of privatization. As of 2007, a majority of municipalities in Sonora were under private land tenure while the majority of Baja California lands remain in ejidos. Public land tenure only covers 4% of the entire nation (Bonilla-Moheno et al., 2013).

In 1993 two large biosphere reserves were established in northern Mexico, the Alto Golfo de California y Delta del Río Colorado and the El Pinacate y Gran Desierto de Altar. These reserves were created to protect endangered species both from the Gulf of California and the Colorado River estuary including the vaquita (*Phocoena sinus*), the totoaba (*Totoaba macdonaldi*), the desert pupfish (*Cyprinodon macularius*), and the Yuma clapper rail (*Rallus longirostris yumanensis*).

The vaquita is a small and elusive porpoise that occupies a limited range in the northernmost reaches of the Gulf of California and is considered the most endangered marine mammal in the world. Its population has plummeted due to entanglement in fishing gear, including in nets set for the totoaba, a large and endangered fish endemic to the Gulf. Totoaba swim bladders are illegally exported to Asia to make soup perceived to have medicinal properties. In 2011, a single bladder could reportedly sell for between \$2500 and \$10,000.

The high demand for totoaba has meant more vaquita drowning as bycatch and the population has plummeted from 567 individuals in 1997 to less than 20 in 2018. In response to international pressure, in 2015 Mexico announced a ban on gillnets, with exemptions for two fish species (curvina and sierra), in the Gulf to protect the vaquita. But the remoteness of the Gulf—ringed by high cliffs and dotted with hundreds of desolate islands—has made it challenging to police, particularly given the involvement of drug cartels in the illegal totoaba trade. Attempts to capture vaquita to establish a captive breeding program have so far failed. If drastic action is not taken soon this species will disappear forever.

Fig. 13 Map of protected areas of the Sonoran Desert by Curtis Bradley. Data Sources: Ecoregions 2017 © Resolve (Sonoran Desert Ecoregion), Reveal from the Center for Investigative Reporting (Border Wall), World Database on Protected Areas, Protected Areas Database of the US (Protected Areas).

United States

Despite the significant population pressures in the United States, large tracts of Sonoran Desert are protected from human development because they are managed by the US federal government as either public lands: Bureau of Land Management, National Park Service, US Fish and Wildlife Service or military lands (Department of Defense).

Various US federal government agencies manage lands under different protocols to conserve resources. Congressionally designated wilderness areas are managed to minimize human imprint and prevent activities such as land conversion, road construction, power lines, pipelines, and off-road vehicle use. Wilderness areas and national monuments administered by the Bureau of Land Management typically allow cattle grazing within the desert. US Department of Defense lands are typically not thought of as protected areas but do provide valuable restrictions on human development, off-road vehicle use, and cattle grazing. National parks, monuments administered by the National Park Service, national wildlife refuges, and some state parks are managed to protect the flora and fauna of the Sonoran Desert and don't allow cattle grazing or other desert harming activities. Organ Pipe National Monument, Saguaro National Park, Anza-Borrego Desert State Park, and Tucson Mountain Park are excellent places to see the desert preserved in a relatively untouched state.

The future of the Sonoran Desert

The most critical threat to the flora and fauna of the Sonoran Desert is climate change, which is predicted to bring with it increasing temperatures and a shift in the timing and amounts of rainfall to the region. Although there is evidence that similar changes may have happened in the past and the desert has adapted accordingly, the rate of change was over millennia, not decades as is predicted under our current climate trajectory.

Unlike climate change, which needs to be addressed at a global scale, habitat destruction can be prevented if local governments and private citizens organize to protect the desert they love. An example of this can be found in southern Arizona with the Sonoran Desert Conservation Plan. This multispecies conservation plan has a goal of ensuring the long-term survival of Pima County's native biota through maintaining the habitat conditions and ecosystem functions necessary for their survival. It was developed over a 20-year process among diverse stakeholders that balanced the conservation and protection of cultural and natural resources with efforts to maintain an economically vigorous and fiscally responsible community. The plan requires continued citizen involvement to make sure it is implemented in a region that is experiencing some of the fastest population growth in the country. And while threats to the desert's biodiversity such as invasive species, the border wall, livestock grazing, and groundwater pumping are challenging, the result of inaction is equally severe with the vaquita serving as an example of when self-centered economic interests are allowed to rule our future.

Abstract

Occupying over 140,000 km² (54,000 mi²), the Chihuahuan Desert is the second largest desert in North America and includes much of the Mexican states of Chihuahua, Coahuila, Durango, Zacatecas and San Luis Potosi, as well as large parts of New Mexico and the Trans-Pecos region of Texas in the U.S. Of the arid ecoregions in the world, the Chihuahuan Desert ranks at the top with regard to plant diversity. This incredible ecoregion is also noted for its endemism, with over 670 species of plants and nearly half of its freshwater fish found nowhere else in the world. The Chihuahuan Desert faces a variety of threats, including habitat loss and fragmentation, climate change, changing wild fire regimes, and deterioration of its freshwater resources. We review these threats as well as the conservation response to them, which includes a diversity of public-private partnerships operating at regional to local scales. We conclude with a summary of conservation priorities for the future, which highlights the importance of a binational response that directly addresses the main drivers of decline, is based on lessons learned from past conservation efforts, expands natural resource monitoring, and builds on momentum of small scale conservation efforts for greater impact.

Introducing the Chihuahuan Desert

The Chihuahuan Desert is the most biologically diverse desert in the Western Hemisphere and one of the most diverse arid regions in the world (Cotera et al., 2004). From north to south, the ecoregion extends nearly 1500 km (932 miles), with its northern extent just south of Albuquerque, New Mexico to its southern extent in the Trans-Mexican Volcanic Belt, which lies just 250 km (155 miles) north of Mexico City. Occupying over 140,000 km² (54,000 mi²), the Chihuahuan Desert includes much of the states of the Chihuahua, Coahuila, Durango, Zacatecas and San Luis Potosi, as well as large parts of New Mexico and the Trans-Pecos region of Texas, making it the second largest desert in North America (Fig. 1).

The Chihuahuan Desert has hot summers and cool to cold, dry winters. The moisture sources that affect the Chihuahuan Desert's climate most are the Sea of Cortez and Gulf of Mexico. Surrounding mountain masses and the position of the desert in the center of the continent results in little frontal precipitation. As a result, the Chihuahuan Desert has a high percentage of its precipitation falling in the form of monsoonal rains during the summer months. With average annual precipitation typically ranging from 150 to 500 mm (6 to 20 in.), this desert has more rainfall than many warm desert ecoregions (Schmidt, 1979).

Distinctive habitat types in the Chihuahuan Desert include yucca woodlands, playas, gypsum dunes, and a diverse array of freshwater habitats. Isolated by the high mountains of the Sierra Madre Oriental, the Sierra Madre Occidental, and the Arizona-New Mexico Mountains, the portion of the Chihuahuan Desert of high Mexican Plateau is rich with endemic species, particularly plants and reptiles (Hernandez and Barcenas, 1995; Gómez-Hinostrosa and Hernández, 2000). For example, a recent study found endemic plants comprising 67 families, 263 genera, 671 species and 155 infraspecific taxa (73 subspecies, 79 varieties and 3 additional hybrids), making a total of 826 taxa (Villarreal-Quintanilla et al., 2017). These results align well with an earlier study that documented

Fig. 1 Location and extent of the Chihuahuan Desert ecoregion alongside two of its ‘sister’ North American deserts, the Mojave Desert and Sonoran Desert. The binational region of Big Bend (discussed later on in this article) is delineated by square. Map from the Desert Landscape Conservation Center.

over 1000 endemic plant taxa (Johnston, 1977). Highlands have significantly higher woody plant diversity than lowlands throughout the region, and physiography is a major control on woody plant diversity (Montaña, 1990; Gómez-Hinostrosa and Hernández, 2000; Poulos and Camp, 2010). Tall mountains and rugged topography provide habitat characteristics conducive to vertical stacking of biotic communities, which amplifies the biodiversity of the Chihuahuan Desert’s montane ecosystems.

Grasslands comprise a small part of the Chihuahuan Desert but are vital to the biological diversity of the ecoregion (PACP-Ch, 2011). Characteristic grasses of the Chihuahuan Desert are tobosa (*Pleuraphis mutica*) and black grama (*Bouteloua eriopoda*) but other common species include alkali sacaton (*Sporobolus airoides*), big alkali sacaton (*S. wrightii*), mesa dropseed (*S. flexuosus*), blue grama (*B. gracilis*), sideoats grama (*B. curtipendula*), hairy grama (*B. hirsuta*), slender grama (*B. filiformis*), chino grama (*B. brevistata*), spruce top grama (*B. chondrosioides*), bush muhly (*Muhlenbergia porteri*), several three awns (*Aristida* spp.), and fluff grass (*Dasyochloa pulchella*) (Johnston, 1977; Dinerstein et al., 2000).

Reptile diversity in the Chihuahuan Desert is impressive and well-documented (UTEP Museum, n.d.; Prival and Goode, 2014; Cruz-Elizalde et al., 2014). Two orders of reptiles occur in the Chihuahuan Desert: Testudines (turtles) (Fig. 2) and Squamata (lizards and snakes), with the latter order being particularly diverse. Seven families of lizards have been recorded in the Chihuahuan Desert region. The Gila Monster (*Heloderma suspectum*) is one of only two known poisonous lizards worldwide, though its range barely overlaps with the Chihuahuan Desert (touching the northwestern portion near the Arizona/New Mexico border) with most of its range is in the Sonoran Desert. The grand majority of snake species (suborder Serpentes) in the Chihuahuan Desert are in the family Colubridae, which are nonvenomous. In contrast, the coral snake (Family Elapidae) is venomous with two species occurring in the eastern and western fringes of the Chihuahuan Desert: the Eastern Coral Snake (*Micrurus fulvius*) and the Western Coral Snake (*Micrurus euryxanthus*). The more familiar venomous snakes in the region are the pit vipers (Family Viperidae), which includes five rattlesnakes. The name comes from the presence of a pit between the eyes and nostrils that contains receptors for infrared radiation (heat) that allow tracking of warm-blooded prey.

A striking number of endemic freshwater fish occur in the Chihuahuan Desert—nearly half of the species in the ecoregion are either endemic or of limited distribution. Most of these are relict pupfish (Cyprinodontidae), shiners (Cyprinidae), livebearers (Poeciliidae), and Mexican livebearers (Goodeidae) found in isolated springs in the closed basins of the region. One of the better-known aquatic basins is Cuatro Ciénegas in central Coahuila, but other significant areas of endemism include the Rio Nazas, Media Luna, the Guzman Basin (Miller, 1977; Minckley, 1984; Minckley et al., 1991), and the Pecos Plain. At least one undescribed species of

Fig. 2 Two turtle species of the Chihuahuan Desert biome that are of conservation concern: western painted turtle (*Chrysemys picta*) (lower) and the Big Bend slider (*Trachemys galgae*) (upper). Photo by John Karges, The Nature Conservancy.

trout (*Oncorhynchus* sp.) occurs in the Chihuahuan Desert ecoregion as an evolutionary isolate in headwater streams in the Sierra Madre Occidental (Hendrickson et al., 2006).

There are also far-ranging large mammals such as Carmen Mountain white-tailed deer (*Odocoileus virginianus carminis*), desert mule deer (*Odocoileus hemionus crooki*), bighorn sheep (*Ovis canadensis mexicana*), elk (*Cervus canadensis*), pronghorn (*Antilocapra americana mexicana*), black bear (*Ursus americanus*), mountain lion (*Puma concolor*), and, jaguar (*Panthera onca*) and, perhaps, some released Mexican wolves (*Canis lupus baileyi*). Over 350 bird species have been recorded in this region, and the river corridor serves as a major thoroughfare and/or stopover for birds (Brush, 2005) and other species (e.g., the Monarch butterfly) that migrate between the Americas.

Threats

Of the many threats that face the Chihuahuan Desert, several standouts seem particularly critical and will need to be addressed as part of a multisector, binational response in the future.

Habitat Loss and Fragmentation

Outright loss of habitat and habitat fragmentation throughout the Chihuahuan Desert has been driven by a variety of factors, including agriculture, urbanization, road construction, amongst others. The conversion of native grassland ecosystems to agriculture has been particularly severe. The rate of grassland conversion varies with location. In the central and northern valleys of the state of Chihuahua, analysis of satellite imagery and on-the-ground observations revealed that more than 69,000 ha (170,500 acres) were converted to agriculture between 2006 and 2011. This amounts to an expansion of the agricultural footprint in this region by an annual rate of 6.04% (Pool et al., 2014). If this continues unabated, it has been estimated that grassland habitat in central Chihuahua will disappear completely by 2025 (NABCI, 2016).

Climate Change

One of the few certainties regarding the effects of global climate change is that wet areas will tend to get wetter and dry areas will become drier. There is no more dramatic evidence of this phenomenon than the Chihuahuan Desert. From 1993 to 2005, after the relatively wet years of 1990–1991, the portion of the Chihuahuan Desert within the Rio Grande/Bravo (RGB) (this binational river is often referred to as the 'Rio Grande' in the U.S. and 'Rio Bravo' in Mexico. Hence, Rio Grande/Bravo (RGB)) watershed suffered the most extreme drought in 100 years. The drought not only undermined economic growth and severely stressed the natural environment, it fueled tensions between the US and Mexico over allocation of internationally shared waters (e.g., the Rio Grande/Rio Bravo, which constitutes the international border in the eastern half of the Chihuahuan Desert).

In an analysis of long-term climate data in the northern portion of the Chihuahua Desert, temperatures are projected to continue to increase throughout the 21st century and, depending on future emissions and other factors, the warming may accelerate

(McRoberts and Nielsen-Gammon, 2010). Average temperatures are expected to rise 2 °C–3 °C (3 °F–5 °F) by the middle of the 21st century (Nielsen-Gammon, 2008). When considering interannual variability, even cool years during the middle of the 21st century will be normal or above normal relative to current temperatures.

The effects of climate change on precipitation are much less predictable, with models suggesting a slight decrease in precipitation across much of the Chihuahuan Desert region in Texas. However, changes in precipitation are projected to be much smaller than the natural variability. For a given amount of precipitation, evaporation increases with increased temperatures and this will make future droughts even if rainfall stays the same. Additionally, increased evaporation will create dwindling water supplies and the projected increase in population will further decrease water. This is eye-opening forecast because the majority of precipitation falls during the warm season. Therefore, the availability of water will depend more and more on cool season precipitation, which is normally sparse in this region (McRoberts and Nielsen-Gammon, 2010).

Changes in precipitation and temperature affect biophysical and chemical processes with cascading impacts on all Chihuahuan Desert ecosystems, and with consummate effects on people and wildlife, alike. For example, warmer water temperatures, increased salinization, and low dissolved oxygen, such as are projected for the Rio Grande Basin (Llewellyn and Vaddey, 2013), may increase the likelihood that nonnative aquatic species will invade (Rahel and Olden, 2008; Bond et al., 2008). Longer, more severe droughts could decrease runoff and eliminate ephemeral lakes and spring pools, as well as drive perennial streams toward intermittent flow, and intermittent streams to ephemeral (Grimm et al., 1998; Garssen et al., 2014).

Changes in Wildfire Regimes

Fire regimes in the region have shifted dramatically over the past two centuries. Prior to Euro-American settlement, frequent, low-intensity surface fire prevailed across most of the dry woodlands and forests of this region (Sakulich and Taylor, 2007; Poulos et al., 2009; Poulos et al., 2013). Starting in the early 20th century, fire exclusion from livestock grazing and then active fire suppression led to a precipitous decline in fire frequency (Swetnam and Betancourt, 1990). Today, more than a century of mounting fuel loads in combination with intensified aridity have sparked a regional surge in catastrophic fires (Dennison et al., 2014; Westerling et al., 2006; Abatzoglou and Williams, 2016). Like the fire suppression era before it, this new fire regime is well outside the historic range of variation for most grassland, semiarid woodland and forest types in the American Southwest and has contributed to large-scale shifts in species composition and structure (Poulos et al., 2013).

Deterioration of Freshwater Ecosystems

Water is important in any context, but is particularly so in the Chihuahuan Desert, where access to sufficient water of sound quality is essential to people and native species, alike. Along the international border between Mexico and the U.S., the Binational Big Bend region of the Chihuahuan Desert is named after the characteristic “bend” in the RGB. Along this border region, the mainstem of the RGB, itself, and its second largest tributary, the Rio Conchos (Fig. 3) comprise the region’s ecological backbone, providing water, food and shelter for 5.5 million citizens as well as a grand diversity of wildlife. Portions of the RGB river system are estimated to be 150% over-allocated. For example, a study of water supply and demand in the lower RGB basin finds that there will be a 730.3 Mm³ (592,084 acre-feet per year (ac-ft/yr)) supply shortfall (demand minus supply) by 2060, with an additional 106.6 Mm³ (86,438 ac-ft/yr) added to that amount as a result of climate change impacts (BOR, 2013). Groundwater is faring no better; 43 of the Desert’s aquifers are overexploited as they are pumped to supply irrigated agriculture, whose footprint has expanded as more and more native grasslands are converted to cropland.

Although flow from the Rio Conchos rejuvenates the hydrology of the RGB through Big Bend, the river’s hydrograph is highly modified and reflects the impacts of impoundment, channelization, over-allocation of water, and fragmentation (Everitt, 1993). Along the RGB in Big Bend, declines in mean and peak stream flow, combined with a relatively unchanged sediment supply and the invasive giant cane (*Arundo donax*), which has established in dense, almost impenetrable stands along channel margins, have fostered aggradational processes (processes that increase surface elevation as a result of deposition of sediment) that bury high quality native aquatic and riparian habitat (Dean and Schmidt, 2013). Many small tributaries of the RGB system are not faring any better. For example, Terlingua Creek, whose watershed lies just north of the international border in Big Bend, was once a “bold running stream, studded with cottonwood timber and alive with beaver” (BIBE, historical archives). However, mining and agricultural activities during the late 19th and early 20th centuries precipitated the loss of these riparian forests and the many species that depend on them for their survival. Similar changes have occurred in many streams across the Chihuahuan Desert ecoregion.

Conservation Response

High species richness, large numbers of endemic species, and presence of globally rare habitats has identified the Chihuahuan Desert as one of a group of 200 high priority ecoregions worldwide (Olson and Dinerstein, 2002). The conservation response to protect the natural resources of this rich ecoregion ranges from global recognition to binational declarations and initiatives between Mexico and U.S. to smaller scale efforts conducted by a variety of public-private partnerships. Selected initiatives in each of these categories are presented below.

Fig. 3 Idealized map of the Rio Grande/Bravo (RGB) basin, which overlaps substantially with the Chihuahuan Desert biome and whose freshwater ecosystems are critical to sustaining this ecoregion's native species and citizens.

International

There are several international agreements associated with key parts of the Chihuahuan Desert that, in and of themselves, do not protect the areas they are associated with yet serve as rallying points for attracting a diverse governmental and nongovernmental conservation response. One such example is the Ramsar Convention of Wetlands, which is an international treaty (signed in the city of Ramsar, Iran in 1971) that supports the conservation and sustainable use of wetlands globally. In the Mexican portion of the Chihuahuan Desert, there are several important wetlands sites that are recognized by the Ramsar Convention, including: Laguna de Babicora, Rio San Pedro-Meoqui (Fig. 4), Laguna La Juanota, Humedales de Guachochi, Manantiales Geotermiales de Julimes, and the Área de Protección de Flora y Fauna Cuatrociénegas in the state of Coahuila.

Several binational declarations and benchmarks between the U.S. and Mexico underscore the importance of protecting the Chihuahuan Desert's treasured natural resources, particularly along the desert's greater binational region of Big Bend. Although nonbinding, these agreements serve to highlight the Chihuahuan Desert's border region as a binational conservation priority and have attracted a diversity of partnerships and funding that are helping to protect this key portion of the Chihuahuan Desert in the long-term. These binational declarations and benchmarks, include:

2000	Joint declaration signed by Bruce Babbitt (Secretary of State, U.S.) and Julia Carabias (Secretary of Environment, Mexico) '... to improve and conserve the natural resources of the Rio Grande/Río Bravo and associated habitats.'
2009	A joint declaration by the U.S. Secretary of the Interior Ken Salazar and Mexican Minister of Environment and Natural Resources Juan Elvira to conserve this region's important and diverse natural resources.
2010	Joint Statement from President Barack Obama and President Felipe Calderón that recognized the 'extraordinary biological diversity' of the Big Bend region, committing their respective agencies "to manage the region in a way that enhances security and protects these areas for wildlife preservation, ecosystem restoration, climate change adaptation, wildland fire management, and invasive species control."

Fig. 4 The declaration of the Meoqui wetland, which lies along the Rio San Pedro (a tributary of the Rio Conchos, which flows into the RGB at Big Bend), as a Ramsar site has spurred the formation of public-private partnerships and attracted outside funding that have greatly helped to protect this critical wetland site for people and wildlife in the long-term. Photo by Alfredo Rodríguez, WWF-Mexico, with permission.

National

Within the portion of the Chihuahuan Desert that lies in Mexico, the Mexican government has established a mosaic of eight protected natural areas that are managed by Comisión Nacional de Áreas Naturales Protegidas (CONANP) to protect key scenic and ecological values of the Chihuahuan Desert. The conservation focus of each of these areas differs with geography, biotic communities and the priorities of the people living in these areas. On the U.S. side of the Chihuahuan Desert, there are numerous conservation and recreation areas managed by the Forest Service, National Park Service, Fish and Wildlife Service, Bureau of Land Management as well as areas managed by the states of New Mexico and Texas. For example, across from the expanse of protected areas managed by Mexico in the Big Bend binational region, Big Bend National Park is bracketed by two natural areas managed by the Texas Parks and Wildlife Department: Big Bend Ranch State Park and Black Gap Wildlife Management Area. Together with the protected areas managed across the river by CONANP, the footprint of these protected areas covers over 13,000 ki^2 (5000 mi^2) (Fig. 5). The conservation importance of the RGB through the Chihuahuan Desert is further recognized by the river's designation as Wild and Scenic (managed by the National Park Service on U.S. side of the river) and Monumento Natural (managed by CONANP on the Mexican side of the river).

Local—Examples From the Field

Working with private landowners

Given the amount of land in the Chihuahuan Desert that is in private hands, collaboration between the private sector and the conservation community is key to protecting the Chihuahuan Desert. Two efforts are highlighted, below, to offer a taste of the plethora of community-based conservation work that is taking place in this remarkable ecoregion.

Working with ranchers to stem soil erosion in the upper Rio Conchos

Overgrazing, urban development, expansion of agricultural, road development, mining, amongst other human interferences have altered vegetation cover and accelerated soil erosion and loss from upper watershed surfaces (Rodríguez-Pineda et al., 2017). In Mexico, federal agencies, and such nongovernmental organizations like World Wildlife Fund, Mexico (WWF-Mexico), have worked collaboratively with private landowners to implement a variety of conservation efforts to stem soil erosion. For example, working with upland ranchers and farmers (those without irrigation rights), this collaborative public-private partnership constructed berms to slow soil loss on 10,230 ha (25,280 acres) of priority Chihuahuan Desert uplands between 2004 and 2010. A critical part of this effort is to provide ranchers, farmers and ejidatarios (members of communally managed lands known as Ejidos) education and training needed to maintain and expand upon these initial successes (Fig. 6).

Water harvesting with Raramuri communities

To engage local citizens in natural resource conservation efforts, the needs of local citizens need to be addressed, as well. Particularly with regard to economically compromised communities, citizens often do not have the luxury to involve themselves in long-term initiatives when efforts to maintain livelihood can be a day-to-day struggle. However, if projects can meet immediate socioeconomic

Fig. 5 Map of the binational Big Bend region of the Chihuahuan Desert, whose central feature is a core of protected areas on both sides of the international border that cover over 13,000 ki^2 (5000 mi^2). Binational restoration efforts have improved biophysical conditions along over 160 km of the RGB (the reach between the two hash marks). See 'Protecting Freshwater Ecosystems,' below. Map by Marie Landis, Big Bend National Park.

Fig. 6 Ranchers in the state of Chihuahua install berms along contour lines to increase water retention and stem soil loss. Photo by Day's Edge Productions.

needs, a foundation for longer term and more natural resource conservation focused efforts can be established. An example of this trajectory is an effort implemented by WWF-Mexico to install water harvesting projects (collecting water off of roof tops for family use and home gardens) in several Raramuri communities in the Sierra Tarahumara mountains of the southwestern portion of the state of Chihuahua. In and of itself, this effort has little to do with protecting Chihuahuan Desert natural resources and all to do with benefiting the well-being of the Raramuri communities. Yet, such community-based work is instrumental in fostering a variety of long-term grassland and forest restoration efforts in the subbasins that are part of the Raramuri lands. In addition, water harvesting efforts that began with Raramuri communities are now being replicated in other parts of the Chihuahuan Desert (Fig. 7). The bottom line: such community-based efforts are key to private engagement and toward expanding conservation efforts for greater impact.

Fig. 7 Community-based water harvesting projects such as this one in the community of Paseo de San Antonio (near the U.S.-Mexico international border) stemmed from work conducted with Raramuri communities and provides great incentive for larger community involvement in a range of conservation activities. Photo by Javier Ochoa-Espinosa (Área de Protección de Flora y Fauna Maderas del Carmen).

Understanding and managing changing fire regimes

Managers throughout the region agree that reducing the risk of destructive, uncharacteristically severe forest wildfires is a priority. Although the actions needed to mitigate this risk vary with location, the reduction of tree density and surface fuel loads is often put forward as central objectives (CEC, 2014). To accomplish these objectives, prescribed fire, forest thinning, and their combination are some of the few tools managers have to manage the surface and aerial fuel array in fire-adapted forests (Schwilk et al., 2009; Stephens et al., 2009).

Studies on the results of fuels hazard mitigation treatments have been carried out at a range of sites on the US portion of the Chihuahuan Desert, including the Guadalupe Mountains, Davis Mountains, and Big Bend National Park (Poulos and Gatewood, 2013; Poulos et al., 2019a,b). Results from these studies suggest that there are tradeoffs associated with carrying out either prescribed fire, forest thinning, or their combination. Resource managers throughout the region need more comprehensive information about the consequences of alternative management practices involving fire and mechanical/manual fuel reduction treatments in a range of upland sites in the Chihuahuan Desert. Work to this end is ongoing, and managers are continuing to experiment with fuel reduction activities at all of the aforementioned sites with the goal reducing management risk and uncertainty of catastrophic wildfire to the greatest degree possible.

Protecting freshwater ecosystems

Native fish conservation

In spite of being well-adapted, many native freshwater fish of the Chihuahuan Desert are threatened or endangered, often due to human actions that have altered streamflow and their natural habitat. There are several efforts that are specifically aimed at protecting the native freshwater fish of the Chihuahuan Desert. On the U.S. side of the ecoregion, stream restoration efforts have been conducted to benefit the threatened Pecos Bluntnose Shiner (*Notropis simus pecosensis*) (Hoagstrom et al., 2008) and to reintroduce the Rio Grande silvery minnow (*Hybognathus amarus*) (USFWS, 2010; Edwards, 2005). In Mexico, the waters of the Rio Conchos provide life to a great diversity of native freshwater fish, many of which are endemic (De la Maza-Benignos, 2009). In the upper part of basin, the Conchos Trout (*Oncorhynchus* sp.) is the only native Mexican trout known from an Atlantic drainage (Hendrickson et al., 2006). WWF-Mexico in collaboration with federal agencies and local communities are protecting the last known refuges of this species through a combination of watershed-based upland and bottomland conservation actions.

An essential part of this work is protecting the streamflow that the Conchos Trout and other native fish depend on for their survival. In pursuit of this goal, 10 sites in the Rio Conchos basin were selected as priorities to define federally mandated environmental flow prescriptions that will protect water needs of local citizens as well as native aquatic species, including the Conchos Trout. Although challenges to protecting streamflow for environmental purposes are formidable, progress is occurring. For example, the large irrigation district of Delicias is working to implement environmental flow prescriptions that will be sustainable for both irrigated agriculture and Rio Conchos trout.

One of the most threatened fish of the Chihuahuan Desert (possibly in the world) is the Julimes pupfish (*Cyprinodon julimes*). Rarely more than 5 cm (2 in.) long, the Julimes pupfish lives in hot-spring waters that reach 45.5 °C (114° F), earning it the title of the “hottest fish in the world.” The Julimes pupfish is endemic to the hot springs of the small municipality of Julimes, where

a population of several thousand fish—along with a tiny snail that is its main food source—survives in an area of about 745 square meters (8000 sq. ft) (De la Maza-Benignos, 2009) (Fig. 8). To protect the hottest fish in the world, a unique partnership developed between NGOs (Pronatura Noreste and WWF-Mexico), several private foundations, and management agencies. To date, this partnership has realized several key accomplishments that include: (i) restoring suitable habitat for the pupfish; (ii) having the hot springs nominated as a global Ramsar site; and (iii) working within the Mexican National Water Law of 1992 to establish and protect minimum flow requirements for the pupfish.

Binational effort to bring back the Rio Grande/Bravo in Big Bend

A centerpiece of the portion of the Rio Grande/Bravo (RGB) watershed that lies within the Chihuahuan Desert is the remote Big Bend binational area. Three protected areas in the U.S.—Big Bend National Park, Big Bend Ranch State Park, and Black Gap—and three in México—Cañón de Santa Elena, Ocampo and Maderas del Carmen—protect over 1 M hectares (over 3800 mile²) of relatively intact Chihuahuan desert habitat and a 290 km (180 miles) reach of the Rio Bravo (Fig. 5). With few road access points, this reach of the RGB that passes through this region is considered one of the great wilderness rivers in North America.

As noted previously, by the early 2000s, dense, almost impenetrable stands of giant cane have become established along many streams and rivers of the Chihuahuan Desert, including parts of the RGB in Big Bend. In response, a binational partnership that consists of federal and state land and water managers, nongovernmental organizations, private foundations, businesses, and river-side citizens designed and implemented a restoration program whose aim is to (i) significantly reduce the extent and dominance of giant cane along the Big Bend reach of the river; (ii) monitor results and conduct needed science; and (iii) work with land and water management agencies to improve water management that better reflects the needs of native stream ecosystems and the riverside communities along this critical binational river (Fig. 9). To date, the binational partnership has restored over 160 km (100 miles) of both sides of the Rio Grande/Rio Bravo in Big Bend.

Working with ranchers to protect key Rio Grande/Bravo tributaries

Restoring native aquatic and riparian habitat along tributaries of the RGB has become an important binational conservation priority. Given that many of these streams are on private lands, working with ranchers on solutions that will benefit them as well as the environment is essential. In Mexico, CONANP is working with local communities to bring back several key small tributaries of the RGB that have been degraded by mining, overgrazing, pollution, and introduction of nonnative species. The diverse conservation campaign that CONANP has launched includes environmental education (with particular attention on the importance of water and water harvesting strategies), scientific studies on current conditions and trends, and restoration and monitoring. An example of this response is restoration work along the streams of San Carlos and San Antonio streams, which are tributaries of the RGB and together drain an area of roughly 2000 sq. km (772 sq. miles). Restoration along these tributaries has centered on controlling nonnative plants and fish (e.g., saltcedar (*Tamarix* spp.) and the plains killfish (*Fundulus zebrinus*)), planting native riparian trees, and working with local communities to improve livestock management and waste water treatment. Similar work is also being conducted along tributaries in the U.S. portion of the Chihuahuan Desert.

Fig. 8 Visitors tour the Julimes hot springs. Ecotourism is a key component of this community-based effort to protect the Julimes pupfish in the long-term. Photo by Alfredo Rodríguez (WWF-Mexico).

Fig. 9 Prescribed burn of dense stands of giant cane along the Rio Grande/Bravo in the binational region of Big Bend (right). Binational efforts to improve conditions along the RGB have been conducted along over 160 km (100 miles) and demonstrate that stream restoration in complicated sociopolitical landscapes is not only possible but can produce substantial win-wins for people and the environment. Looking to the Future

The Chihuahuan Desert embodies the challenges of a new era in which the unsolved natural resource issues of the 20th century meet the 21st century's global challenges of security, development, and conservation. It is a place of clashing cultures, economic dynamism, political strife, and a natural environment under increasing pressure. It is also a place of rare opportunity, where a confluence of political will, scientific and policy advances, stakeholder engagement, and a unique mosaic of conservation efforts on both sides of the US/Mexico border have set the stage for adaptive watershed management that integrate social and ecological resilience to overcome water scarcity and support the development of a green economy. But the Chihuahuan Desert is a very big place. Where best to concentrate our efforts across this expansive ecoregion? Fortunately, social and political events, as well as the collective experiences from a range of past and on-going conservation efforts can help point us in the right direction. As we look to the future, key conservation priorities for the Chihuahuan Desert should include the following considerations:

- (1) *Stop the Bleeding!* Whether we are considering the Chihuahuan Desert's montane forests, desert scrublands, grasslands, or fresh water ecosystems, the first rule of conservation is the same: identify and eliminate (or reduce the impacts of) the main stressors that are causing ecosystem decline. Our ability to do this may be the most important fork in the conservation road. If the major stressors cannot be addressed, it is likely that we will be left working on the fringes, making only minor progress toward real improvement. On the other hand, if a main stressor is eliminated or its impacts are significantly reduced, there may be great potential for dramatic improvement of ecologic conditions at a much larger scale with consummate win-wins for people and wildlife.
- (2) *Scaling Up for Greater Impact:* There are parts of the Chihuahuan Desert where the pieces are in place for a much more ambitious effort to address the environmental, social and economic challenges at landscape scale. One good example is in the Big Bend region where binational restoration work along the RGB coupled with protected areas on both sides of the river (both sides of the international border) offer great opportunities for expansion. How such conservation/restoration expansion will be funded is a key question. One funding avenue that needs to be explored is how future conservation and restoration actions could be supported by binational ecotourism, which could increase under a regional strategy that aligns with conservation goals identified by agency managers and local communities. In general, ecotourism could be enhanced with greater attention to public outreach that emphasizes the importance of the Chihuahuan Desert as a stopover and/or destination location for such species as land bird migrants (Macías-Duarte et al., 2009; Finch and Yang, 2000) and the Monarch butterfly (Jepsen et al., 2015) that are appealing to the public and offer the potential of bringing in much needed conservation funding.
- (3) *Strengthen Support of Existing Federal and State Protected Areas:* As noted earlier, numerous state and federal protected lands are scattered throughout the Chihuahuan Desert. Regardless of where these protected areas occur and the entity that manages them, cuts in staff and resources over the years have left many in a precarious position that threatens their ability to realize their conservation mission and goals. Strengthening of federal (as well as state) conservation budgets on both sides of the border has to be a priority.
- (4) *Expand Public-Private Partnerships and Binational Collaboration:* With the above point made, it is also important to note that governments will not be able to address threats to the Chihuahuan Desert ecoregion on their own. Although diverse and numerous, the total area under federal or state protection is miniscule when compared to the entire footprint of the Chihuahuan Desert. Therefore, one of the keys to protecting the natural resources of the Chihuahuan Desert is alignment,

cooperation and collaboration between the conservation community, the private sector (communities, Ejidos, private land-owners, businesses, farmers, and ranchers), land and water managers, and academic institutes. Building off of momentum gained from public-private partnerships that have already been created and have a track record of conservation accomplishments is key. The diverse mix of agencies, organizations, institutes, businesses, and communities that are working together to protect the natural resources along the border region provides an example of what is needed for the future to protect the Chihuahuan Desert ecoregion as a whole.

- (5) *Protect Biodiversity Hotspots*: Biodiversity hotspots in the Chihuahuan Desert have been identified and should rise to the top as conservation priorities. These hotspots include:

- *Key mountain ranges*: Recent research has identified key mountain ranges in the Chihuahuan Desert that are characterized by high tree species richness—likely due to the complex topography that provides a wide-range of environmental conditions for tree growth—that warrant greater conservation attention owing to both the biodiversity they support and the threats they face (CEC, 2014; Villarreal-Quintanilla et al., 2017).
- *Grasslands*: Given the high percentage of private lands in this ecoregion, protecting intact grasslands and restoring damaged ones will hinge on partnerships with private landowners. In Mexico, more emphasis needs to be placed on working with ejidos (communal land holdings) and Mennonite communities that farm areas that were previously grassland, and/or adjacent to native grasslands. The goal has to be to find ways to manage the land that support the conservation of biodiversity while still meeting the land and food needs of citizens. Past work has identified several grassland dominated areas with particularly high plant diversity (Dinerstein et al., 2000).
- *Wetlands, Streams, and Springs*: Protecting the Chihuahuan Desert's fresh water ecosystems means protecting the water resources that sustain them. The saying, 'water is for fighting, whiskey is for drinking,' underscores the scramble for water between countries, states, agriculture and municipalities that is already occurring in the Chihuahuan Desert as the gap between water supply and demand continues to grow. The environment will be the inevitable loser if we are not able to protect and dedicate water for native ecosystems. Recent binational forums have identified a diversity of efforts already underway to improve management and protect flow for native species and riverside citizens (Briggs et al., 2018). But, more needs to be done to learn from these efforts for greater future impact.

In addition, protecting key wetland, stream, and spring complexes need to be a priority. For example, the wetland complexes in Cuatro Ciénegas has long been held up as a conservation priority. Although parts of this critical wetland complex lie within areas managed by CONANP, the battle over water will require strong public-private partnerships to protect water supplies needed to maintain these critical wetlands in the future.

- (6) *Expand Natural Resource Monitoring*: The uncertain future of the integrity of the Chihuahuan Desert ecosystem underscores the importance of generating baselines for monitoring changes in natural resource conditions of priority conservation targets. Conservation biologists, restoration ecologists, natural resources managers, and local land owners need benchmarks for documenting changes in ecosystem structure and function and for defining best management practices. Although much more needs to be done in this regard, there are on-going monitoring efforts that are documenting hydroecologic vital signs amongst diverse priority conservation areas on both sides of the US-Mexico Border. For example, a 149-plot monitoring network has been established that spans the range of key Chihuahuan Desert ecosystems to evaluate the health and integrity of the region based on photography and vegetation surveys (Poulos and Lozano-Cavazos, 2014). But, more needs to be done and greater attention needs to be given to collecting baseline information and monitoring changes in natural resource conditions and the threats that are driving change.

- (7) *Taking Stock of Past Conservation Efforts*: Numerous conservation efforts of different scales have been implemented by a variety of players across the Chihuahuan Desert ecoregion. The results of such efforts provide an opportunity to take stock and learn from them for future benefit. Pertinent questions, include: How well did these efforts meet their conservation/restoration objectives and what were the key lessons learned from them? What types of efforts and/or strategies and/or mix of entities were effective in meeting conservation objectives? Are the results of these efforts viable in the long-term? Selected examples of past or on-going conservation efforts that we should take stock of are highlighted, below:

- *Community-based conservation*: As mentioned previously, numerous community-based efforts have taken place in the Chihuahuan Desert (e.g., Raramuri communities highlighted, above) that offer a wealth of experience on involving municipalities, Ejidos, local communities, and the agricultural sector in conservation efforts that produces win-wins for people and the environment.
- *Restoration of RGB riverine ecosystems*: Key lessons learned from collaborative, binational work to bring back aquatic and riparian habitat along the RGB, include the importance of establishing: (i) Strong binational working relationships; (ii) Public-private partnerships; (iv) A mix of near-term tangible conservation objectives while longer term (more difficult) objectives are being pursued. Lessons learned from these initiatives are critical to protecting and bringing back freshwater ecosystems throughout the Chihuahuan Desert.
- *Work with ranchers and farmers*—On-going conservation work with both of these sectors demonstrates how important their involvement is to protecting the natural resources of the Chihuahuan Desert. Working with ranchers to improve livestock management, slow water and soil runoff, enhance recharge is central to improving grassland conditions in many parts of the Chihuahuan Desert. Working with farmers (as well as water managers) to conserve water and improve the flexibility of water management will be central to protecting drops for native freshwater ecosystems as well as the livelihoods of Chihuahuan Desert citizens.

- (8) Share the Good News and Keep the Momentum Going: Although the people and the natural resources of the Chihuahuan Desert face many challenges, there is much good news in the form successful conservation projects, partnerships, and binational initiatives. This 'good news' needs to be shared more broadly both within and outside the Chihuahuan Desert. Three examples of efforts conducted to enhance communication, coordination and collaboration toward key conservation goals in the Chihuahuan Desert are highlighted, below:
- A binational forum on water scarcity in the Rio Grande/Bravo basin, which took place in El Paso in 2017, brought together municipalities, farmers, scientists, natural resource and water experts, conservationists, water and land managers, and community leaders to identify strategies to address water scarcity. Priorities and next steps were identified (Briggs et al., 2018);
 - The International Boundary Water Commission and its sister agency in Mexico, la Comisión Internacional de Límites y Agua (CILA), routinely hold binational forums on water distribution and management as it relates to the water treaties between the U.S. and Mexico. These forums provide excellent opportunities to identify and move forward on solutions to water scarcity;
 - The Rio Grande/Bravo Climate Impacts & Outlook ('The Outlook') monthly newsletter that provides timely climate, weather, and impacts information to stakeholders, researchers, and other interested parties in the Rio Grande/Bravo Basin region of New Mexico, Texas, and Mexico. The Outlook is a product of the North American Climate Services Partnership (NACSP)—an innovative trilateral partnership between the U.S., Mexico and Canada.

Abstract

The desert regions of central and southern Baja California, Mexico, are a subdivision of the Sonoran Desert, and this region has many special characteristics that make it unique in the world's deserts. Over a period of decades, the perennial vegetation of this desert region was mapped at an approximate scale of 5 km. The Baja peninsula has at least three general climate zones that affect the species composition of perennial vegetation. In Baja California (Norte), most of the precipitation occurs in winter, particularly west of the peninsular divide. This zone has vegetation assemblages with affinities to California chaparral. In Baja California Sur, summer precipitation, particularly related to tropical cyclones, prevails, and vegetation affinities to the Sonoran Desert are more apparent, particularly in the prevalence of leguminous trees. Mid-peninsula, and west of the peninsular divide, summer fog offers cooling and moisture to perennial vegetation. The maximum biodiversity of cacti and succulents was found in an area where the zones of predominantly winter rainfall, predominantly summer rainfall, and summer fog intersected. This zone could be unstable in the face of future climate change, particularly the incidence of summer fog in the desert areas.

Introduction

Biodiversity of perennial vegetation, and particularly of cacti and succulent, is important for many reasons to scientists and land managers in the deserts of the Western Hemisphere. Understanding where high biodiversity occurs is crucial to management plans as well as understanding the conditions under which these interesting species grow. Baja California, México (Fig. 1), has long been known as a biodiversity hotspot for cacti and succulent plants in North America (Rebman, 2001). Joseph (1985) referred to Cerro Colorado, a volcanic mountain east of San Ignacio (Fig. 2), as "Succulent Hill" because of the large number of species that occur there. According to Dimmitt et al. (2003, 2005), Cerro Colorado had the highest biodiversity of cacti and succulent plants in the Sonoran Desert and therefore presumably in North America.

The desert region of Baja California is segregated by a complex topography, the highlight of which is the peninsular divide, the mountain range that traverses the peninsula, generally occurring in its center (Fig. 1). The deserts south of Mexicali and east of the peninsular divide are considered a southerly extension of the Colorado Desert of southern California (referred to as the Lower Colorado Desert in Rebman and Roberts, 2012). Roughly south of San Quintín and west of the peninsular divide, extending to about the border with Baja California Sur, is the Central Desert, the middle of which is dominated by the Valle de los Cirios Biosphere Preserve. The Vizcaino Peninsula, from Bahía de los Tortugas on the west to San Ignacio on the east and southeast of the peninsular divide, has the Vizcaino Desert (Rebman and Roberts, 2012). The broad lowlands on the west coast around Ciudad Insurgentes are known as the Magdalena Plains, whereas east of the peninsular divide is the Central Gulf Coast region. Finally, the Cape Lowlands surround the Sierra la Laguna in the cape region between La Paz and Cabo San Lucas (Fig. 1). In slightly broader terms, the northern

Fig. 1 Map of the Baja California peninsula showing major towns and the two states of Baja California (Norte) and Baja California Sur.

desert regions of Baja California have affinities to the California chaparral and Mojave Desert, whereas the southern desert regions have affinities to the Sonoran Desert and tropical deciduous forests of the western Mexican mainland.

As is the case in many deserts, the available floras are typically incomplete. [Wiggins \(1980\)](#) is the only flora with a mostly complete coverage at the time of publication. [Rebman and Roberts \(2012\)](#) discusses many common species in lay terms and, in some ways, is the most complete flora available for perennial vegetation but it lacks treatment of annuals and biennials, which are extremely important in the winter-rainfall regions of the northern peninsula. [Turner et al. \(1995\)](#) has considerable ecological detail and biogeography on common perennial species but is incomplete with respect to many uncommon perennials and all annuals and biennials.

Many investigators have discussed species distributions and biodiversity in Baja California. [Turner et al. \(1995\)](#) mapped many perennial plant, including cacti and succulents, in the Sonoran Desert, including Baja California. [Webb et al. \(2014\)](#) extended the work of [Turner et al. \(1995\)](#) by more accurately mapping the distribution of cirio (*Fouquieria columnaris*) in Baja California. Following [Gentry \(1978, 1982\)](#), [Webb and Starr \(2015\)](#) revised the genus *Agave* in Baja California and provided more accurate distribution maps to those given in Gentry's seminal work. Inspired by [Joseph \(1985\)](#) and [Dimmitt et al. \(2003, 2005\)](#), and extending the work of [Turner et al. \(1995\)](#) and [Webb and Turner \(2015\)](#) used higher spatial resolution mapping to evaluate areas of maximum biodiversity of cacti and succulent plants on the peninsula. Here, we revisit the work of [Webb and Turner \(2015\)](#) and also discuss the spatial biodiversity of non-succulent perennial vegetation.

Methods Used for Mapping Perennial Vegetation

[Webb and Turner \(2015\)](#) discuss the techniques they used to map perennial vegetation in Baja California. Whereas [Turner et al. \(1995\)](#) used an irregular grid spacing of approximately 8 km and lumped their data into blocks of 0.1° of latitude and longitude,

Fig. 2 Aerial view of Cerro Colorado, a volcanic hill east of San Ignacio, Baja California Sur, looking southwest towards the Picachos de Santa Clara in the center distance. Joseph (1985) referred to this locality as “Succulent Hill,” and Dimmitt et al. (2003, 2005) referred to this locality – the entire hill as well as some of the terrain off to the right – as having the highest succulent plant and cacti biodiversity in the Sonoran Desert.

Webb and Turner (2015) documented plant lists at approximately 3–5 km spacing with no data lumping. Although the same region was traversed, an improved network of roads and trails allowed greater access to the landscape and therefore more data. Webb and Turner (2015) had less resolution in southern Baja California Sur (Fig. 1), where the Sonoran Desert transitions into a thorn scrub in the Cape Region, because of extensive agricultural clearing and more difficult terrain in the Sierra de la Giganta. Most of the sampling points were north of the Llano de Magdalena around Ciudad Insurgentes (Fig. 1). Webb and Turner (2015) assembled a data set of 1573 observation points, each of which represented all species documented in an idealized area of 100-m radius with a measurement time of 0.5 to 1.0 h. Additional details are given in Webb and Turner (2015).

Biodiversity is the number of specific types of organisms per unit area. Because it has units of density, rules are required to define an area for comparison, what taxa are included, and the amount of time expended in the search for those taxa. Biodiversity is expected to increase logarithmically with both increasing area and increasing time expenditure; in other words, the rate of biodiversity increase slows as more area is added and as more time is used searching for species. Dimmitt et al. (2003) reported spending several days over multiple trips scouring all of Cerro Colorado, which they estimated had an area of 11 km². They found 44 species in that area over that time, including non-native species and some putative hybrids; in our smaller area and shorter acquisition time, we found 22 taxa.

Categorization of Taxa

Our analysis of biodiversity used rules based on generally accepted taxonomy of species, subspecies, and varieties of cacti and other succulent plants in Baja California (e.g., Rebman and Roberts, 2012). Wilder et al. (2008) discussed biodiversity in the islands on the Sonoran side of the Gulf of California and found that 16% of the perennial flora was comprised of succulent plants in the three categories of xerophytic succulents, semisucculents, and halophytic succulents. We chose a modified approach using the three categories of cacti, succulents, and other “species of interest,” as well as non-succulent perennial vegetation grouped more broadly.

Of 701 total perennial plant taxa that we mapped, 173 taxa (25%) were categorized into cacti, succulents, and other species. Wilder et al. (2008) included halophytes, but in Baja California succulent species within the Chenopodiaceae are not significant with distance from dry lakes, arroyos, or the coastlines. Taxa within the Cactaceae are the easiest group to define. Unlike Dimmitt et al. (2003), we did not attempt to categorize hybrids within the genera *Ferocactus* or *Cylindropuntia* but instead placed any unusual-looking individuals within the species that they most resembled. The definition of succulent plants is more complex. True succulents (e.g., *Euphorbia misera*, *Pedilanthus macrocarpa*) are easily categorized, but other species, such as *Acalypha californica*, are leaf succulents at best. Trees were typically classified as nonsucculents (e.g. legumes) or hemisucculents (Turner et al., 1995). Even though they were included in our species lists, we did not include non-native succulent species. A total of 72 taxa are included in the succulent category.

What is included within the category of “Other Species” is subject to debate, and we generally followed the definitions within Turner et al. (1995), Wilder et al. (2008), and Dimmitt et al. (2003) in establishing this group. For example, *Ficus petiolaris* is included within this group, as are the native palms (*Brahea armata*, *Washingtonia filifera*). The genus *Fouquieria* also is included

here, including *F. columnaris* (the iconic cirio), for reasons discussed in Webb et al. (2014); also see Nilsen et al. (1990) and Carlquist (2001). We had a total of 16 taxa in the “Other Species” category.

Because non-succulent species are rather numerous, we choose not to differentiate them in terms of life form other than to segregate leguminous trees from the remainder. We therefore discuss the biogeography of cacti and succulents with additional discussion of total species biogeography and the distribution of leguminous trees.

Biogeography of the Desert Vegetation in Baja California

Distribution of Agaves

Agaves are a major element of the succulent flora in Baja California, and their distribution is uneven along the peninsula. Webb and Starr (2015) revised the genus *Agave* in Baja California, including the two new species of *Agave turneri* (Webb and Salazar-Ceseña, 2011) and *A. azurea* (Webb and Starr, 2014). Webb and Starr (2015) mapped 23 taxa with 22 endemics and presented maps depicting the species distribution and the relationship among them on the peninsula. Several species are narrow endemics; for example, *Agave gigantensis* is restricted in its distribution to several mesas in the northern Sierra de la Giganta (Figs. 1 and 3), *A. azurea* only occurs in the Picachos de Santa Clara on the Vizcaino Peninsula (Fig. 4), and *A. turneri* only occurs in the Sierra Cucupá in north-eastern Baja California.

Two groups of species with very different ecological characteristics are important to biogeography in Baja California. The *Agave sobria* complex, which extends from the northern Sierra de la Giganta to the Cape region and sea level to approximately 1500 m, is primarily in the summer rainfall area outside of the fog-influenced area. As many as five forms of *A. sobria* occur, and some of these could be new species or subspecies. The *Agave shawii* complex of *A. shawii* ssp. *goldmaniana* and *A. shawii* ssp. *shawii* are distributed west of the peninsular divide. *Agave shawii* ssp. *shawii* occurs in the California chaparral in the coastal fog belt from the US-Mexico border to El Rosario (Fig. 1). *Agave shawii* ssp. *goldmaniana* occurs primarily in the region of summer fog, although inland from the coast, from El Rosario to the border with Baja California Sur, and is very common near Punta Prieta (Figs. 5 and 6). Neither species depends upon summer rainfall, and both could be sensitive to climate change that involves reduction in summer fog.

Ocotillos

Four of the eleven species of ocotillo (*Fouquieria* sp., Henrickson, 1972) occur in Baja California. Three species (*F. splendens*, *F. diguetii*, and *F. burragei*) have wand-like stems with only a short trunk. *Fouquieria splendens* is widespread in the Sonoran Desert of the United States and Mexico, and in Baja California it mostly occurs in the winter-rainfall areas of Baja California (Norte).

Fig. 3 This view to the southeast from the summit of Cerro el Potrero shows an arroyo leading to the Gulf of California in the northern Sierra de la Giganta in Baja California Sur. This region of predominantly summer rainfall has lower floral biodiversity, in part because of climate and because of the minimal soil in this volcanic terrain. Palo adán (*Fouquieria diguetii*) and maguey (*Agave gigantensis*) appear in the foreground of this view.

Fig. 4 This view shows Cerro del Gato in the Picachos de Santa Clara on the southern Vizcaino Peninsula in Baja California Sur. This site, the type locality for a new species of maguey (*Agave azurea*) has 19 species of cacti and other succulent plants, including red-flowered elephant tree (*Pachycormus discolor* ssp. *veatcheana*) in the midground, and chollas (*Cylindropuntia cholla* and *C. alcahes*) throughout the view. This region has frequent summer fog and rainfall, but its low elevation and isolation by the surrounding sandy plains of the Vizcaino Desert create lower biodiversity of cacti and succulent plants compared to more northerly and easterly sites.

Fig. 5 In the plains to the southeast of Punta Prieta, Baja California Norte, biodiversity is relatively low despite numerous endemic and iconic species. This view shows elephant tree (*Pachycormus discolor*) in the right midground and datillio (*Yucca valida*) in the left foreground to background. These species are most common in the winter-rainfall regions of Baja California.

Beginning in southern Baja California (Norte), and extending to the Cape Region (**Fig. 1**), *Fouquieria diguetii* is widespread in the desert vegetation and has limited overlap with *F. splendens* in the Valle de los Cirios. *Fouquieria burragei* is a narrow endemic in north-eastern Baja California Sur.

The cirio (*Fouquieria columnaris*) is an iconic species of the northern deserts of the Baja California peninsula in Mexico (**Fig. 7**). Cirio populations measured in the northern part of its range appear to be declining, and the maximum longevity of this species is about 300–400 years (Bullock et al., 2005; Escoto-Rodríguez and Bullock, 2002). Webb and Turner (2015) found that cirio ranges

Fig. 6 Although the area between Punta Prieta and El Crucero in Valle de los Cirios appears to be rich in cacti and other succulent plants, the biodiversity of succulent plants and cacti here is only moderate. Large cacti and other succulent plants include senita (*Lophocereus schottii*) at center, cardón (*Pachycereus pringlei*) in the right foreground and midground, elephant tree (*Pachycormus discolor*) at left center, ocotillo (*Fouquieria splendens*) in the right foreground, and chollas (*Cylindropuntia cactus* and *molesta*) throughout the view. Although summer fog commonly occurs here, this is a region of winter rainfall.

Fig. 7 A low hillslope east of El Rosario, Baja California Norte. This hillslope has a dense stand of cirios (*Fouquieria columnaris*) on the hillslope in the background with perennial vegetation typical of winter-rainfall regions in the foreground. Among that vegetation is Mojave yucca (*Yucca schidigera*), left foreground, and creosote bush (*Larrea tridentata*) in the right.

from southeast of San Quintín to Volcán las Tres Vírgenes (**Fig. 1**) and from near sea level to about 1500 m in the mountains of the central peninsular divide. Cirio typically occurs with *F. splendens* and in a few places also with *F. diguetii*, which increases the succulent plant biodiversity of those localities.

Of the ocotillos, cirio is the species most linked to climate. Most populations of grow where there is a strong Pacific maritime influence mostly east of the peninsular divide in the winter-rainfall region. While fog generally is a reliable aspect of summer climate, winter rainfall is highly variable (Bullock, 2003), and summer or early autumn rain is occasional but potentially large during incursions of hurricanes (Clark). Fog moderates temperatures, adds moisture, reduces evapotranspiration, and locally

encourages growth of *Tillandsia recurvata* and lichens on the branches and trunks of cirios. In other parts of its range, fog is unusual, rainfall is biseasonal, and temperatures are high during the summer months.

Biodiversity of Cacti and Succulent Plants

On average, cacti and succulent plants comprised 43% of the perennial vegetation in the 1573 sampling points in Baja California and Baja California Sur. Cardón (*Pachycereus pringlei*) occurred at 901 sites, the most of any species, followed by senita (*Lophocereus* [*Pachycereus*] *schottii*) at 898 sites. One or more cholla species (*Cylindropuntia*) occurred at 1190 localities (76% of sites), making one or more of the chollas the most commonly observed succulent plant or cacti in Baja California. The most commonly observed succulent was torote (*Bursera microphylla*) at 478 sites, followed by lomboy (*Jatropha cinerea*) at 392 sites; one or more species of torote (mostly *B. hindsiana* and *B. microphylla*) were observed at 550 sites (35%). One or more species of cacti and succulents were observed at 43% of the sites, emphasizing the importance of this group of plants to the perennial vegetation of Baja California's deserts.

Webb and Turner (2015) provide a list of the sites with the highest biodiversity of cacti and succulents in Baja California. The highest biodiversity (27) occurred at four sites in either the southern part of Baja California (Norte)—for example, Cañon de San Andrés north of Guerrero Negro—or just south of the border in Baja California Sur—for example, Paso de Oeste de Tres Virgenes (Fig. 8). Jointly, these sites have 49 species and are 55% similar in species composition (Webb and Turner, 2015). The only species common to all four sites are *Bursera microphylla*, bisnaga (*Ferocactus peninsulae* ssp. *vizcainoensis*), *Lophocereus schottii*, pincushion (*Mammillaria dioica*), *Pachycereus pringlei*, lady slippers (*Pedilanthus macrocarpus*), pitaya agria (*Stenocereus gummosus*), and pitaya dulce (*S. thurberi*) (Webb and Turner, 2015).

The area with the highest biodiversity of cacti and other succulent plants (≥ 25) is approximately L-shaped and spans the border on the west side of the peninsular divide in Baja California (Norte) and Baja California Sur (Fig. 9A). Despite claims made by Dimmitt et al. (2003, 2005), Cerro Colorado (Fig. 2) had a more modest 22 taxa. A smaller hill to the west of San Ignacio, Cerro las Mulas (Fig. 9B), had 25 taxa. The western slopes of the Sierra de San Francisco, west of Guerrero Negro and northwest of San Ignacio (Fig. 1), also had high biodiversity of cacti and succulent plants (Fig. 9C and D). Other sites with higher biodiversity occurred west and north of this mountain, indicating that Cerro Colorado is on the southeastern side of the region of high biodiversity in Baja California. Most of the sites are within the western foothills of the peninsular ranges at elevations of 100–600 m; the exceptions are Cañón de San Andrés and Mesa al Sur de San Gregorio Viejo at 33 and 874 m elevation, respectively.

The peninsular divide acts as blocking topography to certain types of storms and has a rain-shadow effect for winter precipitation, particularly in Baja California (Norte). On the other hand, tropical cyclones tracking up the Gulf of California during the summer and fall months may be at least somewhat blocked from tracking west owing to that same peninsular divide. As a result of these combined climatic effects, perennial vegetation generally is lower on the east side of the peninsular divide than on the west, but nonetheless complex vegetation associations occur (Fig. 10).

Although we believe we have found the zone of highest cacti and succulent plant biodiversity in Baja California, individual sites with high biodiversity are likely still undiscovered owing to access difficulties in rugged terrain. Highly diverse assemblages are

Fig. 8 Volcán de Las Tres Virgenes, which has a diverse flora of 27 cacti and other succulent plants on its west side. This view of a recent lava flow shows a mature elephant tree (*Pachycormus discolor*) on the right. This dormant volcano has the most southeasterly locality for cirio (*Fouquieria columnaris*) on its northwesterly flank (Webb et al. 2014).

Fig. 9 (A) Climate zones of Baja California, Mexico (following Reyes et al. 1990 and Bullock 2003). The thick blue line represents the approximate zone of high biodiversity of cacti and other succulent plants. Summer fog occurs in most coastal areas of the Pacific Ocean but is most common in the desert areas in the west central part of the peninsula. (B) Aerial view looking west at Cerro Las Mulas, a small volcanic hill west of San Ignacio in Baja California Sur. The southeastern slopes of this hill had 27 species of cacti and other succulents, including some species known only from this locality. In contrast, the sandy plains in the distance have low biodiversity owing to unstable substrates. (C) Hillslopes on the west side of the Sierra de San Francisco have as many as 27 taxa of cacti and succulents, giving this area some of the highest floral biodiversity in Baja California. The plants on this slope include pitaya dulce (*Stenocereus thurberi*) and cardón (*Pachycereus pringlei*) throughout the view; candelabra cactus (*Myrtillocactus cochal*) on the midground slopes, and cirio (*Fouquieria columnaris*) in the left foreground. (D) This view on a mesa north of Miraflores in Baja California Sur shows a typically lush assemblage of cacti and succulents in this high biodiversity region. This mesa, west of the Sierra de San Francisco, typically has summer fog. Maguey (*Agave cerulata* ssp. *subcerulata*) appears in the foreground, cholla (*Cylindropuntia cholla*) appears in the left foreground, and palo adán (*Fouquieria diguetii*) with a ball of tillandsia (*Tillandsia recurvata*) in it appears at left center.

known to occur outside of the L-shaped region we documented (Fig. 9A) owing to the potential for favorable microsites. The Cape Region particularly the foothills of the Sierra la Laguna south of La Paz (Fig. 1), have biodiversity hotspots. We found 25 species of cacti and other succulent plants, including four species of *Bursera*, in a small area near Cabo Pulmo on the Gulf of California (Fig. 11). In this region of summer rainfall, particularly from tropical cyclones, the desert transitions into a tropical deciduous forest, and here the potential for high biodiversity switches from the west side of the peninsula to the drier east coast.

Substrate plays a complex but important role in the biodiversity of cacti and succulent plants. All of the sites with high biodiversity are in areas of complex geomorphology with mixtures of rocky substrate and bedrock. Sites with unstable substrates, such as sand dunes, playa margins, sandy plains, and arroyo margins, had low biodiversity. The site west of Volcán de Las Tres Virgenes (Fig. 8), is in a narrow canyon. Sites on the west slope of the Sierra de San Francisco (Fig. 9D) and north of Miraflores (Fig. 9C) are sloping with rocky substrate and bedrock ledges. At Cerro las Mulas (Fig. 9B), high biodiversity occurs where the toe of a volcanic hill transitions into a sandy plain. However, in a similar but more isolated valley to the south in the Picachos de Santa Clara (Fig. 4), biodiversity is lower. Biodiversity also is lower on homogeneous geomorphic surfaces, particularly sand sheets characteristic of the Vizcaino Desert north of Punta Prieta (Figs. 5 and 6).

Riparian Vegetation

Many riparian vegetation areas in Baja California are typical of what occurs in the Sonoran Desert of Arizona and Sonora, with numerous leguminous trees—mesquite (*Prosopis glandulosa*), palo verde (*Parkinsonia* sp.), and palo blanco (*Lysiloma candida*)—

Fig. 10 In Baja California Norte, east of the peninsular divide at Cuesta de la Ley, biodiversity remains relatively low despite some summer rainfall influence from the Gulf of California. In this view, lady's slipper (*Pedilanthus macrocarpus*) appear in the right and left foreground, torote (*Bursera microphylla*) is at the base of a cardón (*Pachycereus pringlei*) in the left foreground, and cholla (*Cylindropuntia alcahes*) occurs at center.

Fig. 11 Inland from Cabo Pulmo, on the Gulf of California coast southeast of La Paz, cacti and succulent plant biodiversity is high despite the fact that this is a summer rainfall area with little fog influence. Among the many species here are maguey (*Agave aurea*), four species of torote (*Bursera* sp.), four species of cholla (*Cylindropuntia* sp.), and pitaya dulce (*Stenocereus thurberi*).

lining ephemeral channels (Fig. 12). The dense overstory provides habitat for numerous other woody species, particularly wolfberry (*Lycium* sp.), graythorn (*Ziziphus obtusifolia*), and hackberry (*Celtis* sp.). What is unique about Baja California is the abundance of water, either in cienegas or perennial streams, and these reaches can support palms (Fig. 13). Besides the famous date palm orchards near towns such as San Ignacio, native palms occur in many places, most famously at Cataviña east of El Rosario (Fig. 1). Despite the high biomass of perennial vegetation, as well as the large ecosystem services provided by these riparian areas, their biodiversity—at least when the riparian zone is considered in isolation—is low. As will be shown, this changes in settings of riparian vegetation within a narrow bedrock canyon, particularly where summer fog is prevalent (see below).

Fig. 12 This view shows the central Sierra de la Gigante in Baja California Sur in the background and dense vegetation in Arroyo Agua Verde near the Gulf of California. The trees with white bark are palo blanco (*Lysiloma candida*), an endemic to Baja California, and several other leguminous trees and shrubs occur in this view with few cacti and succulents present.

Fig. 13 Palms, in this case California fan palm (*Washingtonia filifera*) and Mexican blue palm (*Brahea armata*), are locally common in areas with dependable water supply. Despite the unusual species present and the riparian setting, this site has low floral biodiversity.

Perennial Vegetation

As previously noted, the two most common perennial species we observed at sites in Baja California were cardón and senita, observed at 901 and 898 sites, respectively, or 57% of the sampling points. Creosote bush (*Larrea tridentata*) and mesquite (*Prosopis glandulosa*) were the most frequently encountered species, observed at 836 and 674 sites, respectively (53% and 43%). Of the 20 species most frequently encountered at sites in Baja California, half were cacti and succulents and the other half were non-succulents.

Fig. 14 At the northern edge of the desert in Baja California Norte, numerous species are crowded together in this region of highest winter rainfall in a transition to more chaparral vegetation to the north. Here, bracketing this laurel sumac (*Malosma laurina*) and cholla (*Cylindropuntia cholla*); pitaya agria (*Stenocereus gummosus*) occurs at center, and datillio (*Yucca valida*) and cardón (*Pachycereus pringlei*) occur in the right background.

Total perennial vegetation generally was highest at sites north of the boundary between Baja California (Norte) and Baja California Sur (Fig. 1). The highest number of perennial species observed in our sampling was 66 at Cañon de San Andrés and a mesa southeast of San Borja, in the zone of mixed summer and winter precipitation with summer fog (Fig. 9A), suggesting that biodiversity of perennial vegetation is somewhat controlled by the number of cacti and succulents observed. However, many of the sites are in diverse topography where ephemeral arroyos pass through bedrock canyons, such as Cañon de San Andrés. Other sites with high biodiversity of perennial vegetation are at higher elevation and represent a transition between the desert and the chaparral in the north (Fig. 14) or mesa tops at about the same elevation as the summer fog belt (Fig. 9C and D).

A total of 23 sites, mostly in Baja California (Norte) and mostly in middle-elevation sites, had 50 or more species of perennial plants. Unlike the high biodiversity of cacti and succulent plants, these sites have little in common geographically and are spread over a large range from west of Volcán de Las Tres Vírgenes (Fig. 8) to the northern edge of the desert northeast of El Rosario (Fig. 1). All of these sites are west of the peninsular divide. Low biodiversity sites, excluding barren areas, generally have 2–5 species and are much easier to characterize. Sandy plains, such as the Vizcaino Desert east of Guerrero Negro, tend to be dominated by halophytes such as Palmer's seaheath (*Frankenia palmeri*), and these sites only have 2–5 perennial species in general.

Climate and Perennial Plant Biodiversity

The standard explanation for high biodiversity, and especially high endemism, is geographic isolation over geologic time. This explanation might be useful for explaining unique plant assemblages over the entire peninsula of Baja California, but is not useful for discussing the geography of perennial plant biodiversity. In the desert regions of Baja California, climate and topography interact to produce biodiversity hotspots or to create low biodiversity zones. What is unique about this desert is the influence of summer fog and its influence on the cacti and succulent distribution.

The climate of Baja California is extremely variable seasonally and interannually (Bullock, 2003), which severely limits analysis that might link climatic and biodiversity. In general, the zone of high biodiversity of cacti and succulent plants occurs where precipitation is bimodal (Reyes Coca et al., 1990) and summer fog helps to increase relative humidity in summer and cool the desert. Proximity to the Pacific Ocean and on-shore winds are the most important characteristics of climate in the zone of high biodiversity. Summer fog is uncommon on the eastern side of the trans-peninsular ranges and the Gulf of California. The interaction of geography and fog, combined with two seasons of precipitation, determines where high biodiversity is to be expected.

The geography of persistent fog is difficult, perhaps even impossible, to quantify for Baja California, but in general the top of the maritime clouds in the central peninsula appears to be at an elevation of about 500 m, with dense fog occurring regularly at altitudes of about 250–500 m. This altitude ranges varies widely along the peninsula and through the seasons, but generally maritime-influenced species adapted to high humidity, such as lichens and the epiphytic tillandsia (*Tillandsia recurvata*), occur within this elevation band. The upper 500-m limit of maritime fog irregularly occurs in the foothills of the peninsular divide, creating

innumerable microclimates sustaining high biodiversity. Unlike along the coast, fog in the foothills of the peninsular divide may dissipate early in the day, modulating temperatures and increasing humidity but not greatly reducing solar insolation.

Although outliers exist, most high-biodiversity sites are between 300 and 600 m elevation on west- or southwest-facing sites where fog can accumulate in the morning hours on a regular basis. Cacti and succulent plant biodiversity at the sites of highest biodiversity are strongly influenced by fog. *Myrtillocactus cochal* and *Opuntia* sp., which generally occur in areas influenced by summer fog far to the north of the desert regions of Baja California, are notable at the high biodiversity sites (Webb and Turner, 2015). The presence of *Cochemia maritima* and *Echinocereus maritima*, as well as two *Dudleya* taxa, also attests to the maritime influence.

Species strongly affected by maritime fog occur with other desert species with wider climatic tolerances, such as *Pachycereus pringlei*, *Lophocereus schottii*, and the *Cylindropuntia*. Dimmitt et al. (2003, 2005) discussed how Cerro Colorado had a mixture of floral elements that represented a narrow local environment with species from both the northern and southern deserts. High biodiversity in essence is chance on either the scale we used or that of Dimmitt et al. (2003, 2005); random occurrences of taxa whose distributional centers lie long distances away aggregate to create highly diverse assemblages of cacti and other succulents.

Long-Term Threats to the Desert Vegetation of Baja California

Outside of the urban centers of Tijuana, Mexicali, and La Paz (Fig. 1), Baja California largely has largely a pastoral economy based on livestock grazing with some major centers of agricultural production. These centers—especially near San Quintín and Ciudad Insurgentes (Fig. 1)—are one of the biggest threats to the desert regions. These centers rely on groundwater pumping for irrigation and also benefit from summer fog to lower temperatures and evapotranspiration. It is uncertain whether large-scale agriculture would encroach further into the desert regions.

Although its climate historically has been highly variable, climate change is expected to strongly affect the peninsula. How climate change will alter cacti and succulent plant biography, or perennial plant distributions in general, is largely speculative. Within the extremely variable data (Bullock, 2003), it would appear that winter rainfall has decreased in the last few decades. Continued decrease could affect species composition at the northern edges of the desert (e.g., Fig. 14) and upper elevation limits of the desert along the peninsular divide. Information on the incidence of summer fog is lacking, but anecdotal information suggests that fog has also decreased, leading to higher summer temperatures and solar insolation in some areas. Incursions of tropical cyclones, especially hurricanes, are too episodic to reveal trends in their effects on summer rainfall and perennial plant biodiversity.

Climatic change may have a wide range of species-specific effects instead of changes at the assemblage level. Webb et al. (2014), discussing possible threats to the iconic cirio, suggested that its ability to grow over an extremely wide range of climatic conditions suggests that cirio may not be as heavily impacted as other endemic species with more-specific climatic requirements. Cardón is another species unlikely to be severely impacted by climate change. Species highly adapted to the fog-influenced coastal areas of Baja California, such as *Myrtillocactus*, *Dudleya*, some *Cochemia* and *Echinocereus*, and, of course, lichens and tillandsia, are likely to be the most negatively affected species over the short term.

Summary

The desert regions of Baja California, Mexico, are a subdivision of the Sonoran Desert, and this subdivision is noteworthy in particular for its abundance of cacti and succulent plants. We made species lists at 1573 points in the desert regions, mostly north of the Llano de Magdalena in Baja California Sur. Of 701 total perennial plant taxa that we mapped, 173 taxa (25%) were categorized into cacti, succulents, and other species and 43% of the total perennial vegetation at all sites were in this category. This vividly illustrates the importance of cacti and succulent plants in the flora of Baja California's deserts.

The biodiversity of perennial vegetation—particularly cacti and succulent plants—is controlled by the complex climate of the peninsula. Areas where only winter or only summer precipitation occur have lower biodiversity in general than does the area where summer and winter precipitation occur and particularly where summer fog cools the landscape. Climate change that shifts the summer fog belt could have a serious impact on biogeography of the peninsula. Other pressures on the desert landscape of Baja California include agricultural clearing in several important areas, urban development, and the possible decrease in winter precipitation in Baja California (Norte).

Acknowledgments

A large number of scientists and volunteers helped to collect plant lists in our company between 2001 and 2015. We especially thank Mario Salazar-Ceseña for his numerous contributions to this work, especially the collection of plant lists in the Sierra la Libertad.

Abstract

The Great Sandy Desert (394,900 km²), Gibson Desert (156,300 km²), and Little Sandy Desert (110,900 km²) are three important desert regions within the much larger Australian Arid Zone which covers ~70% of the continent. The three adjoining deserts are characterized by very hot temperatures and low rainfall (averaging 250–350 mm per annum) which is highly variable from year to year, and strongly seasonal (summer-dominant). Sand-dune systems, sandstone mesas and rocky plains dominant the landscapes; the vast majority of these (92% by area) being covered by hummock grasslands (*Triodia* spp.) with scattered eucalypt trees (*Eucalyptus* and *Corymbia* spp.) and *Acacia* shrubs. Plant diversity is relatively high for deserts (over 2000 plant taxa known), with only two threatened plant species recognized to date. Diversity of reptiles and birds is also relatively high, but many small- to medium-sized mammals have been lost from these deserts or are near extinction. Despite the almost complete lack of vegetation clearing across these deserts, and the mostly good to excellent condition of the vegetation, there are still insidious threats to be managed, including widespread wildfires, feral animals and uncontrolled grazing, and weeds. Levels of protected land are well above-average globally (covering some 43% of the area), but are relatively low in terms of formal conservation estate (for instance only 7% for the Great Sandy Desert). Most (85%) of the protected lands across the three deserts comprise Indigenous Protected Areas which provides a means to effectively manage the threats and safeguard natural assets over large expanses of these deserts provided there is adequate and ongoing support given to the Aboriginal custodians.

Location and Introduction

Three large adjoining deserts spread from near the coast of north-west Western Australia to central Australia: the aptly named Great Sandy Desert, the remote Gibson Desert and the Little Sandy Desert (Fig. 1). In many respects these are classic Australian deserts of red sand dunes and rocky gibber plains covered by hummock grasses and sparse white-barked eucalypts and acacia shrubs. The boundaries used to delineate these deserts in this review are the bioregions of the same names (Fig. 1), as defined by Thackway and Cresswell (1997). Of these, the Great Sandy Desert (GSD) bioregion is by far the largest covering some 394,900 km², followed by Gibson Desert (GD; 156,300 km²) and Little Sandy Desert (LSD; 110,900 km²). The Great Victoria Desert, which is reviewed in this volume, lies immediately to the south (Fig. 1).

The three deserts mostly correspond to series of old sedimentary basins which have experienced occasional inundation by sea and extensive in-fill by sediments over millions of years, much of which have been consolidated into sandstone and other sedimentary rocks. Today they feature extensive sand dune systems and isolated rises and ranges with vegetation mostly comprising hummock grassland and *Acacia*-dominated shrublands. Rainfall is typically higher than deserts on other continents (ranging from 350 mm in the north to 250 mm in the south) but this is offset by extreme variability from year to year and very high

Fig. 1 Map of the three desert bioregions (Great Sandy Desert, Little Sandy Desert, and Gibson Desert) and major biophysical features including towns and geophysical features mentioned in the text. Inset shows Interim Biogeographic Regionalization for Australia (IBRA) regions across Australia with three desert bioregions shaded. temperatures and evaporation rates. Consequently the vegetation cover is typically open but not as sparse as many deserts on other continents and large wildfires can occur under the right conditions (Burrows et al., 1991; van Etten and Burrows, 2018).

Biophysical Environment

Current Climate

In contrast to the rest of Australia, the region has very sparse and temporally limited meteorological data with only four active weather stations either within or immediately adjacent to these deserts (Table 1). Climate graphs showing monthly averages of rainfall and maximum temperature are presented at Fig. 2, with annual averages shown in Table 1. Interpolation of these and other meteorological data show that mean annual rainfall is around 350 mm in the northern part of the GSD and broadly declines with distance south to an average of around 250 mm in the southern GD and LSD (Table 1; Beard and Webb, 1974). Median rainfall is some 30–40 mm lower than mean rainfall, mainly because a small number of extreme rainfall events (typically generated by tropical cyclones which regularly develop off the north-west coast of Australia and occasionally cross into these deserts) has skewed the mean rainfall. These cyclonic rainfall episodes can be responsible for 100–300 mm of rain over the course of a few days and are a major contributor to the very high to extreme interannual rainfall variability of these deserts (Table 1; van Etten, 2009). There is also strong evidence that rainfall in recent decades has been above long-term average (O'Donnell et al., 2015).

Rainfall is clearly biased to summer-autumn and again tropical cyclones (or remains thereof) play an important role here, but there is also some monsoonal influence especially in the northern part of the GSD (for instance, rainfall at Balgo is much more summer dominated than other weather station sites; Fig. 2), but otherwise thunderstorms are responsible for much of the rain in summer and autumn. Rainfall is possible in each month, but spring (August to October) are typically very dry (Fig. 2).

Table 1 Average and variability in rainfall at four available meteorological stations in or adjacent to the three desert regions.

Rainfall variable	Balgo	Telfer	Walungurru	Carnegie
No. of years	68	45	22	63
Location, region	Tanami Desert, near GSD	Western GSD	WA-NT border, GSD	Gascoyne region, near GD
Mean	356.4	370.9	293.9	242.2
Std dev	172.8	181.8	178.0	122.1
CV	48.5	49.0	60.6	50.4
Median	327.7	331	269.8	229.3
90th percentile	560.7	621.5	487.6	403.2
10th percentile	159.4	179.5	108.4	97.7
VI	1.22	1.34	1.40	1.33

CV, is coefficient of variability; VI, is variability index (calculated by 90th–10th percentile/median).

Data from Bureau of Meteorology, Australia (www.bom.gov.au/climate/data).

Fig. 2 Monthly means of maximum daily temperature (line) and rainfall (bars) for the four meteorological stations within or immediately adjacent to the three deserts (see Table 2 for locations and annual averages). Graphs constructed by author using data obtained from Bureau of Meteorology, Australia (www.bom.gov.au/climate/data).

Temperatures are typically very hot in summer (January–February daily maxima average almost 40 °C across the three deserts) and are mild in winter (maximum temperature averages 20–25 °C in July; Fig. 2). Occasional frosts can occur in winter away from the coast. Pan evaporation varies from 3600 to 4200 mm per year, which is some 10 times greater than annual rainfall and the highest in Australia (Beard and Webb, 1974).

Climate History

The aridity of the region gradually emerged over millions of years in response to the northward migration of the Australian continent into drier subtropical belts and progressive constriction of the Indonesian Throughflow as the Australian and Asian plates collided, which largely separated Pacific and Indian Ocean circulation and reduced transport of atmospheric moisture across north-west Australia (Christensen et al., 2017). This also corresponded to a time of general global cooling and drying. By the start of the Quaternary Period (~2.4 Ma) the transition from humid to arid climate was complete with seasonal (monsoonal) precipitation

due to orbital forcing now a feature (Pillans, 2018). Characteristic landform features of these desert regions, such as extensive dune fields, salt lakes and restricted drainage, also emerged at this time, although these became more widespread and well developed during glacial periods of the Quaternary (i.e., ice-ages) when the climate was even more arid (Fujioka and Chappell, 2010).

Geology and Landforms

Consistent with being old sedimentary basins, the geomorphology of the three desert regions comprises recent unconsolidated sediment (mostly wind-blown sand dunes and water-shifted alluvia) over thick sedimentary rocks (mostly sandstones). The GSD is dominated by Quaternary red sand dunefields overlying Jurassic and Cretaceous sandstones of the Canning and Amadeus Basins. In places the sandstones form gently undulating laterized uplands. In addition, calcrete and evaporite surfaces associated with occluded palaeo-drainage systems traverse the desert and now feature chains of salt lakes and salt pans (Fig. 1). In contrast, the LSD is dominated by stony hills, low ranges and plains with alluvial deposits in valleys, although the western side has extensive dune fields and sandstone ranges similar to that found in the GSD. The Gibson Desert is mostly covered in fairly uniform and most flat sandy-gravelly sandplain and lateritic “buckshot” gravel plains, with some sandstone mesas (laterized remnants) of again Jurassic and Cretaceous age. Quaternary alluvia associated with palaeo-drainage lines occur across all three deserts (Beard and Webb, 1974).

Vegetation

Major vegetation types for the three deserts were derived from the structural formations and vegetation descriptions of Beard et al. (2013) aided by interpretation from original vegetation maps and reports for the Great Sandy Desert (Beard and Webb, 1974), Pilbara (Beard, 1975), and Great Victoria Desert (Beard, 1974) map sheets. These major types of vegetation are described below (with recognized subtypes) and are mapped in Fig. 3.

Fig. 3 Map of major vegetation types of the three deserts regions (available for Western Australia only). Map produced by author using data from Beard, J. S., Beeston, G. R., Harvey, J. M., Hopkins, A. J. M. and Shepherd, D. P. (2013). The vegetation of Western Australia at the 1: 3,000,000 scale. *Explanatory memoir, Conservation Science Western Australia* 9, 2013, 1–152.

Hummock grasslands

By far the most widespread vegetation type covering some 92% of the study area is hummock grassland which dominates the sandplains, dunes, and lateritic plains. These grasslands are dominated by the grass genus *Triodia*, commonly known as hummock grasses due to the distinct rounded mounds or “hummocks” these grasses form as they age, which is believed to be a graminoid lifeform unique to arid and semi-arid Australia. The grasses can be quite old (generally forming a ring with bare/dead center when they several decades old) and are colloquially known as “spinifex,” although this name is not preferred here given there is also a grass genus *Spinifex* common to coastal dunes. Sparse to very sparse trees and/or shrubs are common to these grasslands (so they are rarely pure grasslands), and in some situations patches of denser tree/shrub stands can develop to form a landscape mosaic with hummock grassland (but as the latter is typically more widespread in these areas, they are mapped here as hummock grassland). The composition and structure of these trees/shrubs define the subtypes as described below (termed tree or shrub steppe depending on which life-form is the most common emergent of the grasslands):

- (a) Tree steppe of desert walnut (*Owenia reticulata*) and bloodwoods (*Corymbia* spp. such as *C. chippendalei*, *C. opaca*, and *C. aspera*) common on dune systems in the northern part of the GSD;
- (b) Tree steppe of desert oak (*Allocasuarina decaisneana*) on dunes and sandplains of northern GD and eastern GSD;
- (c) Shrub steppe of mallee (various *Eucalyptus* spp. with multistemmed form 1–5 m high) often with sparse *Acacia* shrubs;
- (d) Shrub steppe dominated by *Acacia* spp. of various sizes and density (including *A. aneura* s.l., *A. pachyacra*, *A. ligulata*, *A. maitlandii*, and *A. dictyophleba*), but also *Grevillea* and *Hakea* spp.;
- (e) Shrub steppe of *Aluta maisonneuvei* (Myrtaceae) which develop as thickets of low shrubs within a broader mosaic of hummock grassland which likely develops in response to fire absence (Wright, 2018).

Shrubland

This vegetation type is dominated by shrubs 1–5 m tall with at least 30% cover and an open ground layer mostly comprising annual and perennial bunch grasses and forbs, especially after rain. Shrubland covers 3.1% of the deserts by area with three major subtypes:

- (a) Teatree scrub comprising dense stands of *Melaleuca* (mostly *M. lasiandra* and *M. glomerata*) in claypans of dune swales and adjacent to saltlakes receiving freshwater runoff (nonsaline); mostly found in western GSD;
- (b) Mulga shrubland or scrub dominated by *Acacia aneura* s.l. mixed with other *Acacia* species and commonly occurring on stony hills and plains in the GD (this vegetation is similar to Mulga woodlands as described below but differs in the dominance of shrubs rather than trees);
- (c) Mixed *Acacia* shrubland involving many *Acacia* species, such as *A. pachycarpa*, *A. monticola*, and *A. orthocarpa*, on rocky plains and lateritic outcrops.

Mulga woodland

These are woodlands dominated by mulga *Acacia aneura* s.l. trees (generally single-stemmed and 2–10 m high) predominantly found in southern parts of the LSD and GD (Fig. 3) mostly in alluvial soils of large drainage systems and red loams over hardpans. Mulga woodlands are the most common type of vegetation in the Gascoyne and Murchison bioregions to the south, but comprise only 1.5% by area of the three deserts. Mulga woodland is similar to mulga scrub described above but the latter is generally confined to shallow, rocky soils of uplands where the mulga is stunted and generally multistemmed.

Eucalypt woodland

Along the major ephemeral rivers and other major drainage lines throughout the deserts are fringing woodlands of relatively tall trees with a perennial tussock grass understorey. Common tree species include *Eucalyptus victrix*, *E. camaldulensis* and, occasionally, *Corymbia* species. An uncommon vegetation type (<1% by area).

Saltmarsh

This vegetation types develops around salt lakes and major saline drainage systems and is dominated by halophytes from the Chenopodiaceae family, particularly *Tecticornia* spp. (samphire), but also *Maireana* and *Atriplex* species. A sparse to mid-dense shrub layer of *Acacia* and *Melaleuca* develops at some sites. Comprises only 1.1% of the study area.

Salt lakes

Salt lakes of varying size develop in the lowest parts of landscapes where saline groundwater discharges to surface and salts accumulate via evaporation. Some of the large salt lakes of these deserts include Lake Disappointment and Lake Mackay, both of which occur at the lowest point of internal (endorheic) drainage basins. Salt lakes are predominantly bare but can develop sparse annual plant cover in some circumstances. They cover 1.9% of the study area.

Flora

There are over 2000 plant taxa (formerly described species, subspecies and varieties) known from these three deserts, with the most found in the GSD (1788 plant taxa), followed by LSD (1088 taxa), and Gibson Desert (760 taxa), based on Atlas of Living Australia

(ala.gov.au) records. Of these, only 320 plant taxa occur have been recorded in all three desert bioregions, suggesting reasonably high species turnover across these deserts. Common plant families (and genera) are Fabaceae (*Acacia*, *Senna*, *Swainsona*), Poaceae (*Triodia*, *Eragrostis*, *Eriachne*), Malvaceae (*Sida*, *Hibiscus*, *Corchorus*), Asteraceae (*Rhodanthe*, *Calotis*), Myrtaceae (*Eucalyptus*, *Melaleuca*, *Corymbia*), Chenopodiaceae (*Maireana*, *Tecticornia*, *Sclerolaena*), Scrophulariaceae (*Eremophila*), Goodeniaceae (*Goodenia*, *Scaevola*), and Amaranthaceae (*Ptilotus*). Just 35 alien plant species have been collected from these deserts, which is very low given the size of the area concerned; the most widespread and problematic of these is buffel grass *Cenchrus ciliaris* (syn. *Pennisetum ciliare*) which is known to modify fire regimes and fauna habitat where it dominates (Marshall et al., 2012). The number of collected plant taxa is generally lower compared to other Australian bioregions, but it is likely these deserts have been relatively under-collected given their remoteness and lack of large-scale land/resource development (which tends to facilitate biological surveys).

Just two listed threatened plant species are known from these deserts:

- (1) *Seringia exastia*, commonly known as “fringed fire-bush,” is a short-lived shrub typically only found after fire in hummock grasslands; its known distribution is restricted to north-western GSD and adjacent south Kimberley region and its current status is Critically Endangered under State (WA) and Federal legislation (Wilkins and Whitlock, 2016).
- (2) *Thryptomene wittweri*, a shrub from the family Myrtaceae, is listed as Vulnerable by State and Commonwealth governments; very uncommon and only known from western LSD, and northern Pilbara and Gascoyne bioregions.

In addition to these formally recognized threatened species, there are numerous “Priority” plant taxa, which represents those which are currently rare but poorly known due to inadequate data or survey effort. As of February 2019, there were 103 Priority taxa for these deserts of which 39 are Priority 1 (highest priority for future survey). It is therefore likely that more threatened flora will be identified in the future.

Two State-listed Threatened Ecological Communities (TECs) occur in these deserts: (1) the “Mandora Mounds” are small isolated biotic assemblages of organic springs and mounds of the Mandora Marshes located some 140 km south of Broome on the western edge of the GSD (Halse et al., 2005); and (2) “Dragon Tree Soak” being an classic example of a desert oasis in the western GSD supporting a unique vegetation of dense sedgeland with emergent dragon tree (*Sesbania formosa*) (Fig. 1). Both these TECs are classified as “Endangered” based on IUCN criteria and are mainly threatened by grazing and trampling by feral camels and cattle.

Fauna

These three deserts are noted for their richness of reptile species, particularly skinks (*Ctenotus* and *Lerista*), and also have a rich avian diversity (Pianka, 1981; Reid and Fleming, 1992). Mammal species are far fewer in number with many small- to medium-sized species of mammals having been lost from these deserts since European colonization; several of these are either completely extinct or now restricted to off-shore islands. The extinction of these arid zone mammals is an internationally recognized conservation disaster and is likely to have several interacting causes, including exotic predators (cats and foxes), changes in fire regimes and excessive grazing, particularly within refuge areas (Woinarski et al., 2015).

The main threatened mammals still found in the region (based on IUCN Red List) are the: (1) bilby *Macrotis lagotis* (IUCN: Vulnerable) with the dunefields of the LSD and GSD being the mainstay of its current distribution, which was once much wider (Cramer et al., 2016); and (2) black-footed rock wallaby *Petrogale lateralis* (Vulnerable) found scattered across central Australia including the GSD and GD, where it prefers rocky upland habitat. The region also includes captive populations of the mala or rufous hare wallaby (*Lagorchestes hirsutus*; IUCN: Vulnerable as a species complex) which was once widespread across central Australia but, until recently, persisted in the wild only on islands off the Western Australian coast. The loss has been mainly attributable to predation by cats and foxes. However the extant island populations are recognized as distinct subspecies compared to the mainland ones (Eldridge et al., 2019). A unnamed subspecies from mainland central Australia survived via captive breeding and translocations to safe sites, and has been recently re-introduced into predator-proof exclosures in national parks/reserves in its former range in the eastern GSD (including Uluru-KataTjuta NP, Wattaka NP, Newhaven PNP; Fig. 3). Other at risk mammals include: brush tail mulgara (*Dasymercus hillieri*); the Southern marsupial mole (*Notoryctes typhlops*); and the Northern marsupial mole (*Notoryctes caurinus*).

Threatened birds of the three desert regions include the elusive night parrot *Pezoporus occidentalis* (IUCN: Endangered) which was thought to be extinct but recently sighted in the LSD and likely to be elsewhere in region (Olsen, 2018). Its preferred habitat appears to be long unburnt hummock grassland. The princess parrot *Polytelis alexandrae* (IUCN: Near-threatened) is also known from these deserts. Other at risk birds include: Major Mitchell’s cockatoo (*Cacatua leadbeateri*); scarlet-chested parrot (*Neophema splendida*); slender-billed thornbill (*Acanthiza iredalei iredalei*); and the malleefowl, a ground-dwelling megapode found in the southern GD (Vulnerable; *Leipoa ocellata*).

Threatened reptiles of the deserts include the great desert skink *Liopholis kintorei* (formerly *Egernia kintorei*; Vulnerable) which is a large burrowing lizard now restricted to a small number of populations in sand-dune habitat across the eastern GSD, northern GD and Tanami Desert to the north (McAlpin, 2001). Other at risk reptiles include the snakes *Aspidites ramsayi* (woma python) and *Liasis olivaceus* (olive python).

Hydrology and Wetlands

The three desert regions are characterized by low rainfall, high evaporation rates and generally sandy soils, and therefore there are very few permanent surface-water features (the main exception being a small number of surface water seeps and springs).

However ephemeral streams and wetlands exist throughout, with these holding surface water following large deluges, which occur every 5–10 years, with major floods occurring once every 20 years on average, an event which leads to prolific breeding of many species of waterbirds (Halse et al., 2005). Most of the surface water drainage occurs within large endoheric (internal) drainage basins which typically terminate at large salt lakes, such as Lake Amadeus and Lake Mackay (Fig. 1), the latter being Australia's fourth largest lake system. The Rudall River is probably the only true example in the region of an arid zone river with near-permanent wetlands along its course, flowing from uplands to a major salt lake (Lake Dora) within the Great Sandy Desert. Elsewhere a series of interdunal ephemeral wetlands which are dominated by coolibah (*Eucalyptus victrix*) can be found following large rainfall deluges.

There are several recognized Wetlands of National Significance (and other significant aquatic systems) in these deserts (see Fig. 1 for localities):

- (1) Great Sandy Desert: Mandora Marsh; Dragon Tree Soak; Rock Pools of the Breaden Hills; Lake Dora and Rudall River; Lake Amadeus; and Lake Macdonald.
- (2) Little Sandy Desert: Rockholes and Pools of the Carnarvon Range (and other uplands); Saline lakes systems along paleo-drainage lines such as Lake Wilderness and Lake Disappointment; Riparian zone of Savory Creek; and permanent springs of the Durba Hills.
- (3) Gibson Desert: Lake Gruszka, a large (500 ha) seasonal/intermittent freshwater wooded lake; and the Gibson Desert Gnamma Holes, a series of "rock pools," with important ecological, historical and cultural values.

Cultural and Social Context

The three deserts are sparsely populated with most people living in small, isolated Aboriginal communities and settlements. These include Kintore (Walungurru in local language) in the eastern GSD with a population of 400–500, Kiwirrkura (population 200–250) in the northern GD, and three Martu communities (Parnngurr, population 60–80, Kunawarritji, population 100–120, and Punmu, population 90–120) in the LSD and western GSD. Telfer is a mining town in the GSD with around 500 people at any one time, although most mine employees now visit on a "fly-in-fly-out" basis.

The Aboriginal people of these deserts are part of a linguistically linked group known as the Western Desert Aboriginal People who were the last to live as permanent hunter-gatherers in Australia up until the 1980s. A group of nine people were the last to abandon their fully traditional lifestyle in the GSD in 1984. Although there has been consistent migration of desert Aboriginal people, much of it forced, into towns and cities of the region since the 1930s, in recent years small groups of indigenous people have moved back to their traditional country across these deserts, as part of what has come to be called the outstation movement.

Conservation and Management

Threats to Biodiversity

The area is predominantly intact with only minimal amounts of clearing native vegetation and conversion to other land uses. However there are still serious threats to the biota and ecosystems of the deserts from altered fire regimes, nonnative invasive species, altered hydrology, and climate change.

Hummock grasses are generally dense and highly flammable and so the predominance of hummock (spinifex) grassland over the three desert regions (Fig. 3) means vegetation fire is a common, widespread and regular occurrence, with the biota of these grasslands being largely adapted to withstand the effects of fire and/or able to regenerate or recolonize areas after fire (Nano et al., 2012; van Etten and Burrows, 2018). Burrows et al. (2009) studied spinifex fuel dynamics across several sites across the three desert regions and showed that fuel loads increased with time since fire, plateauing at about 10–12 t ha⁻¹ some 18–20 years after fire (van Etten and Burrows, 2018). Typical spinifex fire return intervals are 5–15 years, with fires more common and larger (in terms of area burnt) following wet years (Burrows et al., 1991; Greenville et al., 2009).

Analysis of black and white aerial photography of the GSD from the 1950s demonstrated that the spatial pattern of fires when Aboriginal people lived traditional lifestyles in this region comprised a complex arrangement of many small fires with intervening unburnt areas (Burrows and Christensen, 1990; Burrows et al., 2006). Following the cessation of traditional Aboriginal burning practices across much of these deserts, the fire regime changed from predominantly small, patchy cool-season fires to widespread, intense hot-season fires (Allan and Southgate, 2002; Zeanah et al., 2017). For example, over the period 2000–02, over 500,000 km² of hummock grassland was burnt by wildfire across Central and Western Deserts (Wright and Clarke, 2007), and single summer wildfires can exceed 200,000 ha, burning for several days to weeks (Allan and Southgate, 2002; Burrows et al., 2009). This "boom and bust" fire regime is now largely determined by rainfall which drives the rate of fuel accumulation (Griffin et al., 1983; Allan and Southgate, 2002; Greenville et al., 2009), with lightning now the dominant ignition source. This changed fire regime has been implicated in the decline of small to medium-sized mammals and some bird species, as well as the contraction of fire-sensitive plants, such as native cypress pine (*Callitris* spp.), and vegetation, such as mulga woodlands (Bowman et al., 2008; Ward et al., 2014). It is now accepted that fire sensitive plant species and vegetation were likely to have spread, and perhaps

even protected, under Aboriginal burning regimes, and are now threatened by large uncontrolled wildfires (Wright, 2018). Although Aboriginal burning practices are still practiced in some small areas, they have been recently reintroduced in others in the GSD and GD, and there is evidence that such burning has reduced the number and size of large wildfires (compared to areas without traditional burning; Bliege Bird et al., 2016).

Feral nonnative animals abound in the region and include camels, goats, rabbits, donkeys, and cats. Large herbivores such as camels put extensive pressure on vegetation where they gather, which leads to soil erosion, especially around water points (either natural springs or artificial water points), whilst browsers such as goats damage vegetation across a range of vegetation types (Brim Box et al., 2016). Feral cats (domestic cats, *Felis catus*, which have gone wild) are widespread in these deserts and are a major problem given their prey is mostly native animals, ranging from small mammals, reptiles, birds to invertebrates (Doherty et al., 2015), whilst another introduced predator, the red fox (*Vulpes vulpes*) occurs at relatively low densities throughout these deserts (Burrows et al., 2003).

Although not heavily utilized as yet, the abundant shallow groundwater systems in many parts of the deserts are a potential source of water for irrigated agriculture. Several current proposals to exploit groundwater resources in and adjacent to the western edge of the GSD, mostly involving center-pivot irrigation to produce fodder for cattle, pose an emerging threat to important wetlands in this area, including the Mandora Marshes.

Protected Areas and Land Tenure

Some 43% of the total area of the three desert regions comprise protected areas, with the Gibson Desert having the highest percentage of protected land (58% by area) and the GSD having the lowest (37%; Table 2). The remaining land tenure is mostly UCL (Unallocated Crown Land), ostensibly meaning public land held by the government but not yet allocated for a particular use or designation. There are also several pastoral leases around the edges of these desert, although several of these are not currently kept with domestic livestock (van Etten, 2013). Native title rights exist over the majority of land across the three deserts; this is land for which Aboriginal people have legally recognized rights and interests arising from their traditional laws and customs. Native title can coexist with other types of land tenure.

These proportions of protected land are much higher than many other regions in Australia and most other desert regions globally (Woodley et al., 2012). However, only a relatively small percentage of land is in the most secure IUCN Categories I-IV (National Parks, Nature Reserves, and other areas which are managed primarily for biodiversity conservation), especially for GSD (7% of total area) and GD (18%), which are below and at global benchmarks for levels of conservation-land reservation, respectively (Table 2). Examples of large National Parks (NPs) and Nature Reserves (NRs) include the globally iconic Uluru-Kata Tjuta NP in eastern GSD, Karlamilyi NP which straddles the LSD and GSD (second largest National Park in Australia, formerly known as Rudall River NP), and the Gibson Desert NR (Fig. 4). Newhaven Sanctuary in the north-east GSD is classed as a PNR (Private Nature Reserve) and is an example of a NGO-managed conservation reserve (in this case by Australian Wildlife Conservancy) funded mainly by philanthropy (262,200 ha).

The vast majority (85%) of protected areas across the three deserts are Indigenous Protected Areas (IPAs), a type of protected land recognized and partially funded by the Australian Government and formed by voluntarily agreements with local indigenous custodians. Although they cover a range of IUCN reservation categories, most IPAs are included in IUCN Category VI which allows for sustainable use of resources by the indigenous owners (including fishing and hunting; Table 2; Fig. 4). However some are classed as Category III, such as the very large Birriliburu IPA in the LSD and GD (6.6 million ha), or as Category II (e.g., most of Karajarri IPA; Fig. 4). This reflects the history of some of these areas where they include former conservation reserves

Table 2 Area (ha) of protected areas and other reserves in each of the three IBRA regions of NW Australian deserts divided into IUCN reservation categories as of 30 June 2016.

<i>IUCN category</i>	<i>Gibson Desert</i>	<i>Great Sandy Desert</i>	<i>Little Sandy Desert</i>

which are now under co-management arrangements or other agreements with State conservation agencies. However, several IPAs are formally managed in accordance with more than one IUCN category (e.g., Birriliburu IPA is managed under both IUCN Categories III and VI to enable both traditional resource management and conservation of specific natural features in certain areas). The IUCN category reported and mapped for each IPA (Table 2; Fig. 4) should be that which applies to at least three-quarters of the protected area, the “75 per cent rule” (Woodley et al., 2012), but in reality may simply reflect what is reported to the Australian Government. IPAs generally have been successful in enhancing protection of biota and landscapes, providing land management services (both traditional and ecological) and enabling much-needed employment for Indigenous people (Ross et al., 2009). For example, the traditional owners of the Birriliburu IPA, the Martu people, undertake on-ground management actions to protect and preserve the flora and fauna of the region, which includes reinstating traditional burning patterns, monitoring threatened species and weed control, and they recently established an Indigenous ranger program employing locals from nearby communities (Jupp et al., 2016).

Summary and Conclusions

These three old desert regions of north-west Australia are characterized by similar physical features such as hot climate, highly variable rainfall, and extensive sand dunes, laterized uplands and rocky plains. They contain significant biotic features such as: (1) relatively rich plant diversity (over 2000 plant species); (2) highly threatened fauna, including medium-sized marsupials such as bilby and mala; (3) intact, near pristine vegetation; and (4) large ephemeral playa and other wetlands which burst into life with occasional flooding.

Although the proportion of land in the formal conservation estate (IUCN Categories I to IV) is below international benchmarks (for at least two of these deserts), large expanses of Indigenous Protected Areas effectively means that the natural assets are managed and protected over large expanses of land in these regions. Despite the lack of vegetation clearing and major human disturbances

across these deserts, and the mostly good to excellent condition of the vegetation, there are still insidious threats to be managed, including widespread wildfires, feral animals and uncontrolled grazing, and weeds. Therefore, providing adequate and ongoing support (guidance, finance, infrastructure, employment, etc.) to the Aboriginal custodians is critical to ensure the rich biodiversity values of these deserts are not diminished.

Abstract

The Argentinian Patagonia is a vast area (790,000-km²) of southern South America between 36° and 55°S. Almost 90% of the area is arid, semiarid or dry- subhumid (drylands) and covers important and heterogeneous ecological zones that are determined primarily by climatic gradients and a highly complex geomorphology. That gives rise to different soils (mainly Aridisols, Entisols and Mollisols) and vegetation types (semideserts, shrub steppes, shrub-grass steppes, grass-shrub steppes and grass steppes). Grazing (mainly sheep) and, to a lesser extent, fires are the principal anthropogenic stress factors that have dramatically altered the structure and functioning of these ecosystems. Climatic models predict an increase in aridity for Patagonian drylands, which could accentuate the negative effects of overgrazing on ecosystem health and reduce the capability of Patagonian ecosystems to provide essential services such as forage production and carbon sequestration. The adjustment of grazing management practices could mitigate negative effects but requires routine monitoring of ecosystem structure and functioning, for which the MARAS system (Spanish acronym for 'Environmental Monitoring for Arid and Semi-Arid Regions') has been developed.

Patagonia

Patagonia is a vast area of southern Argentina and Chile (south of South America) between 36° and 55°S. The area covers important and heterogeneous ecological zones that are determined primarily by climatic gradients and a highly complex geomorphology that gives rise to different soils and vegetation types. The boundaries of this region, especially the northern limit, vary according to the criteria adopted, depending on whether it is a biogeographical or political-administrative. This chapter refers mainly to drylands of Argentinian Patagonia (excluding the Andean, humid region, dominated by temperate forests) an area of 790,000-km². We consider the Barrancas and Colorado rivers as the northern limit of this region (Fig. 1).

Climate

The center and western part of the region is dominated by air masses coming from the Pacific Ocean and influenced by the Andes mountains that impose a barrier for humid air masses. These winds ascend the western slope, discharging their humidity mainly in the Chilean sector. West of the Andes, in the Argentine sector, there is a rapid decrease in precipitation from 2000 mm year⁻¹ or more in some sectors of the Andes to less than 200 mm year⁻¹ in a 100-km distance. The seasonal displacement of the low- and

Fig. 1 Location of Argentinian Patagonia.

high-pressure systems and the equatorward ocean current determine the seasonal pattern of precipitation. During winter, precipitation increases over the region due to a higher intensity of the subpolar low, combined with the northward displacement of the Pacific high and higher ocean temperatures relative to the continent. The result is a clear winter-distribution pattern of precipitation over most of the area (Paruelo et al., 1998), with about 46% of precipitation concentrated in winter (Jobbágy et al., 1995) and a strong water deficit in summer. The northeastern and the southern parts of the region are additionally affected by air masses coming from the Atlantic Ocean and present more evenly distributed rainfall (Paruelo et al., 1998). Annual precipitation is <200 mm in 37.5% of the region, while 34.5% of the area shows 200 to 300 mm (this means that 72% of the Argentinian Patagonia has annual rainfall <300 mm). In small areas (3.2%) rainfall can be >1000 mm (Fig. 2). Most of the area (86.7%) may be considered a Dryland since its Aridity Index (rainfall/potential evapotranspiration relation) is <0.65. Within these Drylands, 32.7% is classified as arid, 51.3% as semiarid and 2.7% as dry subhumid (Fig. 3). Isotherms show a northeast to southwest distribution due to the effects of increasing latitude and altitude on temperature. Mean annual temperature ranges from 15 °C in the northeastern to 3 °C in the south (Fig. 4). Patagonia is located between the belt of high subtropical pressures and the area of low subpolar pressures, so it is fully included in the zone of circulation of the winds from the west of the Southern Hemisphere. Westerly winds are characterized not only by their persistence during the year but also by their intensity. Mean annual values of wind speed vary between 10 and 20 km h⁻¹ in the north of the region and between 20 and 30 km h⁻¹ in the center and south part of the region. According to these values, Patagonia is within 5% of the world's windiest lands (Fig. 5). The annual distribution of the wind speed shows a maximum between September and January and a minimum in winter (Paruelo et al., 1998).

Landscapes and Soils

The most characteristic landscapes of Patagonia drylands are the plateaus or *mesetas*. These plateaus decrease in elevation from the Andes towards the Atlantic coast and are usually covered by basalt rocks, the product of volcanic eruptions in the Cenozoic era, or by pebbles or *rodados patagónicos*: rounded rock fragments generated by erosion during water transport during events of snow and ice melting. Volcanic features, hills, plains and fluvial valleys are found between the plateaus. A series of rivers that flow from the Andes to the Atlantic, such as the Colorado, Negro, Chubut, Chico and Santa Cruz. The uplift of the Andes in the Miocene is, perhaps, the most significant event shaping the Patagonian landscapes because it imposed a barrier for moisture from the Pacific Ocean by the prevailing westerly winds. This produced a change in the climate of the Argentinian Patagonia, from moist in the west to arid and semi-arid eastward, creating conditions favorable to wind erosion (Paruelo et al., 2007), that transported large quantities of sediment from the eroding mountains toward the plains and plateaus farther east. These sediments have been the original material and shape the distinctive characteristics of the soils of Patagonian drylands. Nine of the twelve taxonomic soil orders included in the

Fig. 2 Mean annual precipitation (Bianchi and Cravero, 2010) in the Argentinian Patagonia. Bianchi, A.R., and Cravero, S.A.C. (2010). Atlas climático digital de la República Argentina. Instituto Nacional de Tecnología Agropecuaria: Salta, Argentina.

U.S. Soil Taxonomy (Soil Survey Staff, 1999) are present in Patagonia (del Valle, 1998). Two of them are strongly dominant: Aridisols (50%), Entisols (22%). Water deficit is the major defining characteristic of Aridisols as they are soils of dry regions, mostly of deserts. Entisols are soils with little or no evidence of profile development. A series of volcanoes are located along the Andes mountains, especially on the Chilean side between 36° and 46° South, and 50 of them are active or have had an eruption in historical times (Besoaín, 1985). Predominant winds from the west have distributed volcanic material from Chile to the Andean-Patagonian region of Argentina, where soils derived from volcanic ash classified as Andisols (Soil Survey Staff, 1999) comprise 4 M ha or 5% of the region (del Valle, 1998). The marked gradient of precipitation in west-east direction has conditioned the evolution of these soils and generated differential properties (Colmet Daage et al., 1988; Gaitán and López, 2007). Mollisols occupy about 13% of the territory. They generally occur in a north-south belt in the occidental portion of the Patagonian region (del Valle, 1998), in the transition area between the humid sector of the Andes (with Andisols) and the extra-Andean drylands (dominated by Aridisols and Entisols).

Due to water redistribution, induced by the topography, wet meadows, locally known as *mallines* (a Native American word meaning muddy area) occupy the depressed portions of the landscape, such as the drainage lines between hills and plateaus (Fig. 6; Marcolín et al., 1978). Higher water availability in *mallines* leads to the development of azonal types of soils and plant communities (Gaitán et al., 2011b). These ecosystems occupy between 1.5 and 2.0% of the region's surface, and up to 8% in some areas (Mazzoni and Vazquez, 2000; Bran et al., 2004a). Water dynamics in these wetlands show a seasonal recharge of the soil profile in autumn–winter, followed by a progressive decrease in the level of the water table during spring, reaching its lowest value in summer (Cremona and Lanciotti, 1996). Soils of *mallines* are deep, loamy textured and with abundant organic matter.

Vegetation: Description of the Main Plant Communities and Their Relationship With Climatic Gradients

The vegetation of Patagonia drylands includes diverse vegetal communities, that belong to two phytogeographic provinces (Patagonia and Monte) and a wide ecotone between both. It has developed under arid, semiarid and dry sub-humid climates that also show different thermal regimes according to the latitude and the altitude. Table 1 presents in a simplified way the Main Vegetation Units (MVU) and their relationship with these two climatic attributes (aridity index and mean annual temperature), and are delimited in the Fig. 7. Among these MVU, the changes in general are not abrupt, and intermediate vegetation types will be found accompanying the climatic gradients. Physiognomic and floristic variants will be also found according to the types of soil on which they develop, where depth, texture and alkalinity are the main determining factors. Management history also influences vegetation, as overgrazing has generated convergent effect with aridity. Species characteristic of drier environments increase in overgrazed areas, as noted by Gaitán et al. (2018) and this changes ecosystem attributes and function.

Phytogeographic Province: Patagonia

Following the criterion of aridity index, three groups of communities can be considered. In the dry subhumid, grass steppes dominate, in the semiarid the low shrub–grass steppes and in the arid low shrub steppes.

Grass Steppes

Grass steppes dominated by *Festuca pallescentis* (Fig. 8A) are found in the Andes foothills, that show also ecotones in the form of patches or mosaics with the deciduous forest (*Nothofagus pumilio* and *N. antarctica*). These steppes have been called Subandino District (Soriano, 1956; Golluscio et al., 1982). With some variants, they are also found further to the east in very high plateaus or

Dominant species	<i>Larrea divaricata</i> , <i>Prosopis flexuosa</i> and <i>Geoffroea decorticans</i>	<i>Larrea</i> spp., <i>Monttea aphylla</i> , <i>Atriplex lampa</i>	<i>Larrea nitida</i> , <i>Schinus</i> sp., <i>Prosopis denudans</i>	<i>Festuca pallescens</i> (DS) <i>Festuca gracillima</i> (DMX and DMH)	<i>Mulinum spinosum</i> and <i>Adesmia volckmannii</i> (DO) <i>Mulinum spinosum</i> and <i>Trevoa patagónica</i> (DG) <i>Junellia tridens</i> (MN)	<i>Nassauvia glomerulosa</i> , <i>N. ulicina</i> y <i>Chuquiraga</i> spp.

hills (generally above 1200 m a.s.l.). The typical vegetation is a grass steppe with high vegetation cover (60–70%), dominated by *Festuca pallescens* and accompanied by *Rytidosperma* spp., *Lathyrus magellanicus* (Colluscio et al., 1982). Other frequent species are *Agrostis pyrogea*, *Senecio sericeonitens* and *Nassauvia aculeata*. Degradation caused by fire and overgrazing increases cover of shrub species such as *Mulinum spinosum*, *Acaena splendens* and *Senecio* spp. *Rumex acetosella* invasion is also frequent (Franzese and Ghermandi, 2012a).

Other grass steppes dominated by *Festuca gracillima* are found in the south near the Strait of Magellan (Magellanic District, León et al., 1998). Among the *F. gracillima* tussocks a rich stratum of short grasses and herbs such as *Poa spiciformis*, *Bromus setifolius*, *Rytidosperma virescens*, *Carex* spp., *Festuca magellanica*, *Hordeum* spp., *Phlaiophles biflora* and *Armeria maritima* develops. Dwarf shrubs such as *Nardophyllum bryoides*, *Nassauvia ulicina*, dominate degraded areas and in the more humid areas with acid soils the creeping shrub *Empetrum rubrum* becomes important. Other common dwarf shrubs are *Nassauvia fuegiana*, *Perezia recurvata* and *Ephedra frustillata*. The total vegetation cover varies on average between 60% and 80%. Oliva et al. (2001), differentiate two variants, one more xeric (Magellanic Xeric District) and the other more humid (Magellanic Humid District, Fig. 8B).

Low Shrub-Grass Steppes

Low shrub-grasslands steppes develop in the arid and semi-arid areas in a broad area east of the Andes known as Occidental District (Soriano, 1956; Fig. 9A). Vegetation has a cover of 40–60% and distributed almost proportionally between low shrubs (between 0.5 and 1.0 m in height) and tussock grasses, locally called *coirones*. Dominant shrubs are *Mulinum spinosum*, *Adesmia volckmannii*,

Fig. 7 Main vegetation units in Argentinian Patagonia. Modified from León, R., Bran, D., Collantes, M., Paruelo, J. and Soriano, A. (1998). Grandes unidades de vegetación de la Patagonia extra andina. *Ecología Austral* 8, 123–141.

Senecio spp. (mainly *S. bracteolatus* and *S. filaginoides*), *Berberis heterophylla* and *Tetraglochin alatum*. Among the grasses are *Pappostipa* spp. (mainly *P. speciosa*, *P. major* and *P. humilis*), *Poa ligularis* and *Festuca argentina*. The presence of a medium shrub layer is common in rocky soils such as mountain foothills and basaltic landslides where *Colliguaja integerrima* or *Retanilla patagonica* are frequently dominant. Another related shrubs formations are found in the coastal region of the Gulf of San Jorge (Golfo District; Soriano, 1956). They are also shrub-grass steppe with vegetation cover of 40–60%, but shrubs are higher (1.5–2.0 m high), mainly dominated by *Retanilla patagonica* and other shrubs such as *Colliguaja integerrima*, *Mulinum spinosum*, *Anartrophyllum rigidum*, *Lycium* spp., and *Prosopis denudans*. Common grasses are *Festuca argentina*, accompanied by *Poa spiciformis* and *Pappostipa* spp. In the south of continental Patagonia an additional shrub-grass steppe develops, dominated by low shrubs (0.5–1.0 m in height) of *Junellia tridens* (Mata Negra District; Fig. 9B). Other common shrubs are *Nardophyllum obtusifolium* and *Berberis heterophylla*, and grasses forming tussock such as *Festuca pallescens*, *F. gracillima*, *Pappostipa* spp., and *Jarava neai*, are also present. Short grasses such as *Poa spiciformis*, *Pappostipa ibari*, *Festuca pyrogea* and *Rytidosperma virescens* and dwarf shrubs of *Nassauvia glomerulosa* and *N. ulicina*, *Satureja darwinii* and *Ephedra frustillata* are also present in this diverse community.

Sub-Shrubs Steppes

Dwarf or creeping shrubs lower than 20 cm height are widespread in Patagonia. These steppes show low vegetation cover (20% or 30%) and were called Central district by Soriano (1956). Dominant species is the shrub *Nassauvia glomerulosa* but degraded areas include *Nassauvia ulicina* and *Chuquiraga aurea*. Erosion of shallow, duplex soils shows here clay layers and abundant erosion pavements. *Pappostipa* spp. are common grasses. Northern areas show higher, scattered shrubs of *Chuquiraga avellanedae*, *Senecio filaginoides* and *Lycium ameghinoi*. *Acantholippia seriphioides* is also common. Towards the south shrubs of *Junellia tridens*, *Anartrophyllum rigidum*, *Schinus* sp. and *Berberis heterophylla* are also common following drainage lines.

Fig. 8 Subandino district (A) and Magellanic Humid district (B).

Phytogeographic Province: Monte

In the northeastern part of Patagonia, where relatively higher latitudes are combined with relatively low altitudes, vegetation communities belong to the Monte Phytogeographic Province (Cabrerá, 1976), that extends east of the Andes mountains, from North of Argentina to Patagonia, and is characterized by the predominance of medium to tall shrub steppes, dominated by *Larrea* spp.

In the northeastern end of the region, these shrublands show different physiognomy and floristic composition and are classified as “Monte Oriental” (León et al., 1998; Fig. 10A). The genus *Prosopis* (mainly *P. flexuosa* and *P. alpataco*), is here dominant, and there are more C4 grasses such as *Pappophorum caespitosum*, *Setaria leucopila*, *Sporobolus cryptandras*, and *Trichloris crinita*. Total vegetation cover is relatively high (60–80%) and emergent tree layers of *P. flexuosa* (and very sporadically of *P. caldenia*) and patches of *Geoffroea decorticans* are common. Shrubs are dominant, and the most conspicuous species are *Larrea divaricata*, *Condalia microphylla*, *Chuquiraga erinacea* and *Prosopis alpataco*. Grasses are dominated by *Nassella tenuis* and *Piptochaetium napostaense*, *Nassella longiglumis*, *Jarava plumosa* and *Poa ligularis*, in addition to the C4 grasses mentioned above. The area endures recurring fires, which temporarily modify the physiognomy and the relative vegetation cover of grasses and shrubs (Bran et al., 2007).

The rest of the Monte in Patagonia (“Monte Austral”; León et al., 1998; Fig. 10B) is mostly under Semi-arid climate. Vegetation is mostly a shrub steppe that does not exceed 2 m in height, with a total vegetation cover close to 40%. The most frequent species is *Larrea divaricata*, accompanied by *L. cuneifolia* (which dominate in sites of greater edaphic aridity) and *L. nitida* (which becomes more abundant towards the ecotone with the Phytogeographic province of Patagonia). Other frequent tall shrubs are: *Monthea aphylla*, *Bougainvillea spinosa*, *Schinus* spp., *Lycium* spp. and *Prosopis alpataco*, and in the short sub-shrubs *Cassia aphylla* and *Acantholippia seriphioides*. Grass cover depends on grazing pressures, and the most common species are: *Nassella tenuis*, *Pappostipa speciosa*, *Jarava neaei* and *Poa ligularis*. Cover of *N. tenuis* varies greatly depending on the interannual variations of rainfall. In the relatively low positions with higher salinity-alkalinity soils, *Atriplex lampa* dominates, in mixed communities with *Larrea divaricata* and *Larrea cuneifolia*. Where salinity is high and soils have finer textures, *A. lampa* is accompanied or replaced by *Chuquiraga avellaneda*. *Suaeda divaricata* is frequently found on the margins of the salinas. In environments with significant sandy accumulations the dominant species is *Hyalis argentea*, accompanied by *Sporobolus rigens* and *Panicum urvilleanu*.

Fig. 9 Occidental district (A) and Mata Negra district (B).

Patagonia-Monte Ecotone

In the northeast of the region (approximately between 400 and 700 m a.s.l.) an ecotone between Patagonia and Monte (called Ecotono, León et al., 1998) is found with low to medium shrub steppes of *Schinus johnstonii*, *Prosopis denudans* and *Larrea nitida*, usually in “islands” that do not exceed 1.5 m in height, and with a total vegetation cover close to 40%. *Lycium chilense*, and *Junellia aspera* are also common. *Prosopidastrum globosum* is dominant in rocky soils such as those of the basaltic plateaus. Among the shrub “islands”, low shrubs and grasses dominate with *Grindelia chiloensis*, *Mulinum spinosum*, *Senecio filaginoides*, *Nassauvia axillaris* and *Acantholippia serphioides*. The grass stratum is generally poor and dominated by *Pappostipa humilis*, *P. speciosa*, *Jarava neaei* and *Nassella tenuis*. Within shrubs “islands” *Eremium erianthum* is common.

Towards the Northwest the ecotone has been described as the Payunia District (Cabrera, 1976), dominated by shrub steppes that do not exceed 2 m. height of *Ephedra ochreatea*, *Coliguaya integrerrima*, *Larrea nitida*, *Neosparton aphyllum* and *Schinus* spp. An intermediate stratum includes shrubs such as *Mulinum spinosum*, *Stillingia patagonica*, *Senecio* spp., *Grindelia chiloensis* and *Chuquiraga rosulata*.

Southern sector of the ecotone is dominated by *Chuquiraga avellanadae* (Called Ecotono *Chuquiraga avellanadae*; León et al., 1998), with an open high shrub stratum of *Lycium ameghinoi*, *L. chilense*, *Junellia ligustrina*, *Prosopis denudans* and *Schinus* sp. In the lower stratum there are *Acantholippia serphiodes*, *Nassauvia ulicina*, *Pleurophora patagonica*, and *Pappostipa humilis*.

Another interesting vegetation variant is present in the Valdez Peninsula, that shows a shrub steppe dominated by *Chuquiraga avellanadae*, *Chuquiraga erinacea* and *Condalia microphylla* (called Ecotono Península Valdez, León et al., 1998). *Lycium chilense*, *Schinus* sp., *Prosopidastrum globosum* and *Larrea nitida* are also frequent here. The most abundant grasses are *Nassella tenuis*, *Nassella longiglumis*, *Pappostipa speciosa*, and *Piptochaetium napostaense*. *Hyalis argentea* with *Sporobolus rigens* and *Panicum urvilleanum* dominate in very sandy soils.

Native Fauna

Animals native to Patagonia are closely related to those of Australia and New Zealand and in a more distant manner to those of South Africa and North America. Fauna of the Patagonian steppe forms two distinct groups associated with vegetation units of the

Fig. 10 Monte oriental (A) and Monte austral (B).

“Monte” in the north and “Patagonia” in the south, with numerous endemic taxa of great ecological importance (Bonino, 1994). Reptiles are especially abundant in the north, with 109 mostly endemic species, including lizards of genus *Liolaemus* and *Diplolaemus*, 18 species of snakes and a two earth turtles. Excluding marine animals, there are actually nine orders of mammals in the region, with 20 families, 58 genus and 90 species, 77 of which are native and 12 introduced. Some of them are rare endemic marsupials such as the Comadreja overa (*Didelphis* sp.), the Marmosa (*Thylamis* sp.), and the secretive Monito del Monte (*Dromiciops gliroides*). Nine species of Bats (*Histiolus* sp.) are present. The most abundant are rodents with digging habits, with 26 species of mice (*Akodon* sp. and others), Tuco-tucos (*Ctenomys* spp.), Cuises (*Microcavia*), and the “Patagonian hare” or Mara (*Dolichotis patagonum*). The only great herbivore of these steppes is an endemic camelid: the Guanaco (*Lama guanicoe*). Carnivores include the widespread Puma (*Felis concolor*), Gray and Red foxes (*Lycalopex culpaeus*), a Ferret (*Lyncodon patagonicus*), wild cats such as Montés (*Leopardus geoffroyi*) and Pajonal (*L.colocolo*) and Skunks (*Conepatus humboldtii*). Some introduced mammals have become dominant, including the European hare, rabbits, the American mink and the Canadian beaver. Bird life is abundant, with over 300 species (Narosky and Babarskas, 2000), although a great proportion of them are marine or restricted to the Andes. The steppes are habitats for running species such as Rheas or Choiques (*Pterocnemia pennata*), Martineta (*Eudromia elegans*), and Quiula, that is endemic of the region (*Tinamotis ingoufi*). Insectivorous birds such as Bandurrita (*Upucerthia dumetaria*), and Caminera Patagónica (*Geositta antarctica*) are mostly of walking habits and gray or brown plumaje. Wetlands in the desert harbor more eye-catching birds such as the endemic, threatened Macá Tobiano (*Podiceps gallardoi*), Gallineta Chica (*Rallus antarcticus*) or Pato Vapor (*Tachyeres patachonicus*). Anatidae family is more abundant and includes a number of Ducks, Black necked Swans (*Cygnus melancoryphus*) and Upland geese or Cauquen Común (*Chloephaga picta*) and Colorado (*Ch.rubidiceps*), this last one in severe retraction. North of the región and within the Monte vegetation a different suite of species includes Gallito Arena (*Teledromas fuscus*), Canastero Patagónico (*Asthenes patagónica*) and Caserote Pardo (*Pseudoseisura gutturalis*).

Principal Anthropogenic Stressors

Grazing

The influence of grazing in Patagonia has been matter of debate. [Milchunas et al. \(1992\)](#) used the region as an example of short evolutionary history of grazing, but guanacos, the only great herbivores present before colonization, had been grazing these cold semi deserts since the end of the Tertiary, 2 M years ago. [Cabrera and Yepes \(1960\)](#) estimated their populations at about 7 M at the end of 19th century, and [Lauenroth \(1998\)](#) considered that they may have been a significant factor in the evolution of apparent defense mechanisms in spiny shrubs and tough forage. Domestic herbivores were introduced in Patagonia close to 1880, and wild, mobile guanaco grazing was replaced with continuous sheep grazing at fixed, high stocking rates that were only possible after the introduction of fences and water holes in close to 11,000 great units or “*Estancias*.”

It is not possible to reconstruct past carrying capacities of rangelands during the early stages of colonization, but they can be compared to actual carrying capacity estimations based on primary productivity from 2000 to 2015 satellite images ([Oliva et al., 2018](#)). Analysis of historical stock in [Fig. 11](#) shows that sheep increased driving total grazing well over this threshold early in the past century and remained high during six decades. From 1978 onwards they decreased sharply and were only partially replaced by cattle, reducing total domestic stock numbers until they converged to estimated carrying capacity. The process was probably forced by low reproduction rates ([Golluscio et al., 1998](#)) that complicated replacement of stocks during disasters such as volcanic ash, drought or excess of snow ([Andrade et al., 2002](#)). Huge areas of central Patagonia were abandoned and *Estancias* reduced their flocks close at a minimum numbers compatible with commercial production, with great unrest for local livelihoods and the economy of rural towns ([Andrade et al., 2010](#)). Patagonian rangelands showed stability, as they endured over six decades of overgrazing, probably because they were dominated by long-lived perennials ([Oliva et al., 1998](#)). On the other hand, low resilience explains lack of recovery after drastic stock reductions late in the 20th century ([Gaitán et al., 2015](#)), probably because vegetation suffered transitions to shrublands with soil erosion ([Paruelo et al., 1993](#)), that affect close to one-third of the region ([del Valle et al., 1998](#)). Even though present domestic stock seems to have reached a balance with primary production, local misbalances still remain in place. Guanaco populations that were estimated at only 0.6 M in 1990 ([Bolkovic and Ramadori, 2006](#)) have recovered in the last two decades after great sheep destocking, and are now at a 2.2 M, a significant addition to grazing pressure ([Bay Gavuzzo et al., 2015](#)). In conclusion, overgrazing has severely affected soils and vegetation in the region. While sustainable stocking rates may stop degradation ([Oliva et al., 2012](#)), recovery processes of soil, productivity and diversity are very slow, and will probably require in the future joint management of native and domestic herbivores after decades of overuse ([Oliva et al., 2016](#)).

Fires

In many arid and semiarid ecosystems fire is a major ecological force, as in South Africa ([Bond et al., 2003](#)). Although fire seems to have played a lesser role in Patagonia, in some parts of the region fire has shaped vegetation patterns. Wildfires are frequent in two regions of North Patagonia, the Subandino District grass steppes and the eastern “Monte” shrublands ([Bran et al., 2004b](#)). In other areas of Patagonia, especially when vegetation cover is less than 50%, fires are not frequent, and probably in the south part (i.e. Magellanic District) climate conditions inhibit the development of fires.

Fig. 11 Sheep, cattle, goat and total combined stock for Patagonia from 1914 to 2015 in Animal Units (1 AU = 1 cow/year). Shaded area represents carrying capacity ($\pm$ SD) in the 2000–15 period estimated from satellite images. Modified from Oliva, G., Paredes, P., Ferrante, D., Cepeda, C. and Rabinovich, J. (2018). Comparación entre receptividad y existencias ganaderas en La Patagonia. Una aproximación a escala regional. *Resumen VIII Congreso Nacional sobre Manejo de Pastizales Naturales-IV Congreso del Mercosur sobre Manejo de Pastizales Naturales*. 15 al 17 de mayo de 2018 Chamical, La Rioja.

In north-western Patagonia fires are relatively frequent and are influenced by ENSO events. [de Torres Curth et al. \(2008\)](#) studied fires in this region during 1984–2004 and registered only two fire seasons with large burned areas, and both were related to “La Niña” phenomena. [Oddi and Ghermandi \(2016\)](#) characterized the fire regime between 1973 and 2011 for a study area that covers 5,600 km² (40°16′ to 41°11′ South and 70°26′ to 71°01′ West), using a 1973–2011 time series of Landsat images. They determined a total burned area of 72,500 ha which represents 13% of the study area, in 88 different fires. The largest wildfire was of 21,477 ha and occurred in 1999, the year with the most extensive burned area (30,284 ha).

In Post-fire regeneration, the recovery of the original community prevails by persistence of resprouter species and by auto-replacement of species ([Ghermandi et al., 2004](#)), but some other processes that induce partial changes were observed, such as:

- The increase of shrub cover, mainly of *Senecio bracteolatus* ([Franzese et al., 2009](#)) and *Fabiana imbricata* ([Oddi et al., 2010](#); [de Torres Curth et al., 2012](#)).
- Changes in the relative cover between dominant tussock species, locally named “coirones” (*Pappostipa major* and *Festuca pallescens*). This is consequence of differences in post-fire survival (higher in *P. major*), post fire recruitment (lower in *F. pallescens*, due to little protection structures in seeds and lack of self-burial mechanisms compared to *P. major*), as well as changing competitive interactions during post fire regeneration, especially when there is an early post-fire grazing that led to a reduction in *F. pallescens* the more palatable species ([Gittins et al., 2011](#); [Franzese and Ghermandi, 2012b](#)).
- Weed invasion principally of *Rumex acetosella*. This exotic perennial herb invades the area between the “coirones,” and produced notable changes on the “intercoironal” vegetation ([Franzese and Ghermandi, 2012a](#)).
- The establishment of a community of fugitive species. These species that colonizes early from the seed bank have a short life, but are able to recharge the seed bank before the next disturbance and increase diversity. Due to this behavior this group of species, such as *Montiopsis polycarpoides*, *Boopis gracilis*, *Heliotropium paronychioides*, *Nicotiana linearis*, *Chenopodium scabraule* and *Descurainia pimpinellifolia*, was called the “phantom community” ([Ghermandi et al., 2004](#)).

In the “Monte” shrublands, wildfires can affect large areas. [Bran et al. \(2001\)](#) reported 720,000 ha burned during the 2000/01 summer. The biggest continuous polygon of burned areas covered more than 50% of this surface (365,000 ha). The fires could be seen in a Landsat image ([Fig. 12](#)).

Fire and grazing seem to affect the relationship between the dominant functional groups. [Kröpf et al. \(2015\)](#) developed a state and transition model for the eastern Monte with six stable states and 12 transitions, focused on the three most conspicuous layers: shrubs, grasses and biological crust. They concluded that the grass layer is most frequently affected by intensive and continuous grazing, which reduces the occurrence of fires and shifts the equilibrium toward the shrubs. The shrub layer is affected by large-scale disturbances (fire, mechanical clearing) which maintain the balance between grasses and shrubs in the system. History and intensity of these disturbances can explain the different vegetation structures observed in the region.

[Bran et al. \(2007\)](#) studied the effect of burn severity in the early post fire vegetation evolution and observed a faster recovery for vegetation cover in areas with lower burn severity. In sites with high burn severity seed banks were apparently destroyed. In all the cases the grass/shrub cover ratio was higher in burned than unburned areas. High burn severity also affected soil organic carbon concentration ([Gaitán et al., 2007](#)).

Fig. 12 Area affected by wildfires in the “Monte” shrublands, during the summer 2000/2001, seen in a Landsat 5 TM satellite image.

Global Climatic Change Effects

According to the Global Climate Models (GCMs), the expected changes in the climate during this century will not affect in the same way the broad Patagonian region. To evaluate the spatial variability of these changes, we used 17 MCGs presented in the 5th Report of the Intergovernmental Panel on Climate Change (IPCC, 2013), in two scenarios of greenhouse gas emissions (RCP4.5 and RCP 8.5) for the period 2061–80. These models show increases of the mean annual temperature of 2–3 °C in the south of the region and of 4–5 °C in the north in the RCP4.5 scenario. While in the RCP8.5 scenario the changes would be more accentuated: 4–5 °C in the south and 6–7 °C in the north. Mean annual precipitation in both scenarios is expected to decrease, except in the extreme north and south of the region, where increases of up to 10% are projected. Rainfall in Center and west areas is expected to decrease 10–20% (Fig. 13).

Fig. 13 Projected changes in mean annual temperature (MAT) and precipitation (MAP) for the period 2060–80 in two scenarios of greenhouse gas emissions (RCP4.5 and RCP 8.5) for the Argentinian Patagonian region. Based on the current climate (1950–2000) of WorldClim model (Hijmans et al., 2005, <http://www.worldclim.org/current>) and the average of the projections made by 17 Global Climate Models presented in the 5th Report of the Intergovernmental Panel on Climate Change (IPCC, 2013), available at: <http://www.worldclim.org/cmip5>.

Previous studies show that temperature has a negative relationship with grass cover and species richness and a positive relationship with shrub cover across Patagonian drylands (Gaitán et al., 2014a). In addition, temperature affects indirectly and negatively the aboveground net primary productivity (ANPP) of these ecosystems. Lower rainfall is related to lower grass cover, lower species richness and ANPP, and increasing shrub cover (Gaitán et al., 2014a, 2018). These studies suggest that projected increases in temperature and aridity will generate an impact on the structure and functioning of these ecosystems. The expected increases in temperature and aridity suggest an increase in shrub cover, a decrease in total grass cover (mainly in palatable grass species), and a reduction in species richness. In addition, climate change is expected to have direct and indirect effects (mediated by their effects on vegetation structure) on the functionality of these ecosystems. It is likely that ANPP and forage productivity will decrease in Patagonian drylands, and that these ecosystems will be less efficient in converting the precipitation into biomass. Soil functional processes, such as nutrient cycling, infiltration and stability in relation to erosion processes, would also be affected (Gaitán et al., 2018). The increase in temperature and the severity of droughts would also have a negative effect on the ANPP (Gaitán et al., 2014b).

Monitoring System

Long-term land monitoring technology is needed to track slow changes in drylands and evaluate biodiversity, biological invasions, local extinctions and physical or chemical soil variations including carbon storage. Consistent data sets are lacking because researchers and government agencies use multiple techniques to evaluate the same variables. The MARAS system (Spanish acronym for Environmental Monitoring Arid and Semi-arid Regions) is a network for long-term monitoring Patagonian drylands that use a standardized methodology that enable different research teams collaborate across wide geographical areas using a common open data-base (Oliva et al., 2019). This system was developed by INTA at the beginning of the 2000's with the purpose of establishing a regional long-term monitoring system capable of detecting the trend of the desertification process and provide early warnings that would aid management decisions that could slow down and reverse the problem.

Sites were uniform areas with dominant vegetation type and representative management (in sheep farms they were typically ewe paddocks), distant at least 500 m from water sources and roads. Wetlands or other azonal vegetation types were not sampled. The methodology for site evaluation was described in detail in manuals (Oliva et al., 2011), so here it will be briefly summarized: in each MARAS site a photographic pole was fixed and a 72-m central line was laid following the main resource flux direction (wind or water flow direction). Three poles were fixed at 8.5 m along this line, separated perpendicularly 2.5 m and two additional sets of three poles were set at 13.5 and 72 m separated by 6.5 m. Photos were obtained from photographic pole at 2 m height and positions of pole 1 and 9 were registered with GPS. Three 50-m transects were placed, two for vegetation and one for patch structure sampling and Landscape Functional Analysis sampling (Fig. 14).

Vegetation cover was estimated using the point intercept method (Müller-Dombois and Ellenberg, 1974). Along each transect, we recorded the type of ground surface (plant species, bare soil, rocks, cryptogams, standing dead or litter) every 20 cm (500 records per site). Patch structure was analyzed using gap-intercept method described in Herrick et al. (2005) along the soil line. Patches were defined as areas >10 cm that retained resources. They were mostly live plants but occasionally consisted of standing dead or decomposing litter fixed to the soil. Interpatches were areas >5 cm that lost resources, and mostly consisting of bare soil or desert pavement areas. A minimum of 25 and a maximum of 50 patch-interpatch pairs were recorded. With these data we calculate

Fig. 14 Scheme of MARAS monitor and an example of a network site.

structural attributes of the vegetation: basal vegetation cover, average size (width, length and height) and density (number every 10 m) of the patches and average length of the interpatches. Landscape Functional Analysis (LFA) was estimated in plots outlined over the first 10 interpatches that exceeded 40 cm in length along the soil line. This was a modification of [Tongway and Hindley's \(2004\)](#) methodology, where plots were systematically placed at intervals along a line. Eleven soil surface indicators were visually rated using a scale proposed by [Tongway \(1994\)](#) that was modified to suit regional soil and vegetation. From these 11 indicators three LFA indexes were estimated: Stability, Infiltration and Nutrient Cycling. Composite superficial (0–10 cm depth) soil samples were obtained from patch and interpatch areas and tested for pH, electric conductivity, organic carbon, N and texture.

The MARAS network has 380 sites distributed across Patagonian drylands, which were installed and assessed between 2008 and 2017 ([Fig. 15](#)). The first evaluation of these sites allowed generating a baseline that has been recently published ([Oliva et al., 2019](#)) and this ground data has been combined with remotely sensed information ([Gaitán et al., 2013](#)), in order to extrapolate the data. As of 2013 the sites began to be resampled and currently (December 2018) 192 sites have a second evaluation after 69.6 ± 15.1 months of the first. [Fig. 16](#) shows an example of a site with two ground evaluations.

The MARAS network, where soil and vegetation indicators are evaluated in the field, together with climate data and satellite images, give way to a monitoring system that seems to have potential to detect change of biophysical traits of arid lands with a detail and precision that was not possible with multiple techniques and isolated data bases. This system that may be useful in other arid and semiarid areas of the world since it offers a structure to perform sampling, to store and share information between scientists of different countries and institutions ([Oliva et al., 2019](#)).

Conservation Strategies

Patagonian drylands are among the areas of lower human population density, and with less degree of artificialization and substitution of its ecosystems, and the name "Patagonia" evokes romantic images of a windy wilderness at the end of the Earth. But human activities, since the century 19th–20th transition, have forever altered the structure and composition of Patagonian

Fig. 15 Location of MARAS sites network.

Fig. 16 Example of a MARAS network site with two ground evaluations: 12/15/2012 and 4/12/2017. The data of some structural and functional indicators of the ecosystem are shown.

wildlife and vegetation communities, and most of Patagonia is no longer truly wild (Walker et al., 2005). Vegetation and soils have been depredated mainly due to sheep and goat overgrazing, and 80% of its surface is affected by some degree of desertification (del Valle et al., 1998).

In Dinerstein et al. (1995) evaluation of the terrestrial eco-regions of Latin America, the Patagonian Steppe was classified as Vulnerable and of Maximum Regional Priority; and it was one of the 200 world ecosystems classified as priority for conservation (Olson and Dinerstein, 2002). They also consider that Patagonian drylands had not an adequate network of protected areas, with less than 1% of the area under strict protection category and several ecosystems without representation.

In recent years, efforts have been made to change this situation, identifying areas of importance for the conservation of biodiversity (Chehébar et al., 2013) and through creation of National Parks (Monte León coastal-marine National Park in 2004; Petrified Forests of Jaramillo National Park, in 2012; and Patagonia National Park, in 2015). Complementary initiatives aimed to achieving land sustainable management have been carried out, like the Project to Combat Desertification in Patagonia (INTA-GTZ, 1995) and the GEF PNUD ARG 07/G35 Project (Sustainable Management of Arid and Semiarid Systems for Desertification Control in Patagonia, Argentina. 2007–13). This last project provided the resources to install the MARAS environmental monitoring system of the Patagonian drylands.

Rangelands Evaluation for Sustainable Grazing Management

From the decade of 1990 the National Institute of Agricultural Technology of Argentina (INTA) developed a methodology applicable to livestock ranches in Patagonia in order to optimize production without compromising long-term rangelands health. This methodology basically consists in identifying the different types of environments present in a ranch, for which the interpretation and analysis of satellite images is carried out. In the field, vegetation composition, degradation state and forage productivity is estimated based on the cover of palatable species and their status. Animal stocking rate is adjusted according to consumable forage and estimated yearly animal consumption (Borrelli and Oliva, 2001; Elissalde et al., 2002; Siffredi, 2012).

With this forage allowance, animals consume approximately 30% of the total forage biomass, and no more than 50% of the biomass of the most palatable species for sheep. This residual level is considered necessary in order to allow for regeneration according to a practical rule in the rangelands management (Stoddart and Smith, 1955). In controlled grazing trials, rangelands that were under 10 years of animal stocking rate adjusted with this methodology maintained their diversity and increased their total vegetation cover and the cover of palatable grasses and herbs (Oliva et al., 1998).

Concluding Remarks

The Argentinian Patagonia is one of the world's largest rangelands in drylands with heterogeneous vegetation structure and comprehensive climatic variation. Grazing by domestic herbivores is the most widespread human use in the area. Over 100 years of grazing have induced strong changes in the structure of Patagonian ecosystems. Regional models of climate change for the next century predict an increase in arid conditions due to lower precipitation and higher temperatures in Patagonia. These climatic changes are likely to have a negative impact on the sustainability of Patagonian ecosystems due to their strong impact on vegetation structure and functioning. Appropriate management of livestock carrying capacity and the use of rotational grazing can offset or mitigate these negative effects of climate change. Finally, the use of long-term monitoring systems such as MARAS, which integrate field-based surveys, remote sensing, climatic data and a multivariate interpretative framework could be a useful tool to detect and provide range managers and government agencies with 'early warning' signals for the onset of desertification processes due to human use and/or climate change.

Abstract

While not typically thought of as having high biodiversity, deserts are home to many unique and endemic species adapted to arid environments. The Namib Desert, along the Atlantic Coast of southern Africa, is one of the world's oldest deserts and is unique in that it still harbors several megaherbivores. Often overlooked are the nocturnal, volant mammals in this desert—its bats. Here, I conduct the first intensive study of northern Namib bats using both mist nets and acoustic detectors. While bat species richness is typically maximized in wetter, warmer areas, the topographical and vegetative diversity of the Namib supports more species than otherwise expected. I conclude with the primary threats to biodiversity conservation and human-wildlife coexistence in the Namib Desert, including my findings from 86 semi-structured interviews with local pastoralists.

Desert Biodiversity

Deserts are often seen as relatively simple ecosystems characterized by low productivity and species richness (Noy-Meir, 1974; Seely and Louw, 1980; Polis, 1991). Rarely are they considered bastions of biodiversity. Nevertheless, these systems harbor a surprising number of unique species adapted to the harsh and highly variable desert environments that cover 17% of earth's terrestrial surface (Crawford, 1981; Polis, 1991; Durant et al., 2014).

Water plays an important role in structuring wildlife communities (Noy-Meir, 1974), particularly in deserts where precipitation totals—while low on average—show extreme inter-annual variation (von Wehrden et al., 2010). Desert mammal distributions and behaviors are strongly affected by daily water losses (e.g. well digging by elephants; Ramey et al., 2013), though some species are less dependent on access to bodies of water than others (e.g., giraffe; Fennessy, 2009). Many deserts contain rivers, which strongly differ from their mesic counterparts because desert rivers can be almost entirely subterranean or highly intermittent with no flows for years, yet continue to harbor remarkable biodiversity (Young and Kingsford, 2006). Surface water availability concentrates desert life, such that springs in arid landscapes are recognized as global biodiversity hotspots (Brown and Ernest, 2002; Bogan et al., 2014; Davis et al., 2017).

Global Patterns in Species Richness

Globally, species richness tends to decrease with distance from the equator, resulting in a latitudinal gradient in diversity (Hillebrand, 2004). One explanation for this pattern is the “time and area” hypothesis (Mittelbach et al., 2007), which states that the age of a community may enable proliferation of more diverse life forms (i.e., speciation). The tropics may have accumulated species over a longer time than temperate zones due to reduced impacts of the Pleistocene's glacial-interglacial cycles near the equator in comparison to higher latitudes (Stephens and Wiens, 2003). Some areas of the world outside the tropics, however, are also recognized to have a long history of climatic stability.

Among arid zones, the Namib along the Atlantic coast of southern Africa is considered to be one of the world's oldest deserts (Fig. 1). The Namib is a 50–150 km wide coastal desert stretching over 2000 km from the Rio Bentiaba (São Nicolau; 14°16' S; 12°22' E) in Angola across Namibia to the Olifants River in South Africa (31°42' S; 18°11' E) (Werger, 1978; Henschel and Lancaster, 2013). While the current ecological state of the Namib is thought to have developed during the Pleistocene Epoch at the start of the Benguela Upwelling System (Walter and Breckle, 1984), evidence from a geological review suggests that this desert was never more

Fig. 1 The Namib Desert meeting the Atlantic Ocean. Courtesy Emsie Verway.

humid than semi-arid for at least the last 55–80 million years (Ward et al., 1983). Perhaps owing to this antiquity and historical stability, the majority of Namibia's endemic and near-endemic flora and fauna are found in the Kaoko escarpment of the northern Namib Desert, which is considered to be the most important endemism hotspot for vertebrate taxa in Namibia and Angola (Simmons et al., 1998). The region has remained a relatively stable center for the evolution of desert species and adaptations to arid conditions.

An Overview of the Namib Desert

The Namib comprises several phytogeographic subdivisions (Jürgens et al., 1997). These include the northern Namib, central Namib plains, central Namib dunes including the Namib Sand Sea, and the southern Namib, which branches into the East Gariep Namib inland, and the northwestern Namaqualand Sandveld along the coast. Major geomorphic features include mountain ranges and river canyons in the north (Fig. 2), which give way to gravel plains interspersed with inselbergs and mountain outcrops (Seeley and Pallett, 2008).

Large sand dune systems (i.e., the Kunene Sand Sea, the Skeleton Coast dune field, and the central Namib Sand Sea) are found throughout areas of the desert, but particularly dominate the land forms in the southern and parts of the central Namib. The entire desert is characterized by high winds, extreme daytime temperatures, and almost negligible rainfall (Parker and Lawrence, 2001).

A key ecological driver of species diversity among these habitats is water availability. In parts of the Namib Desert, water occurs as frequent coastal fog (as many as 200 days per year in the central Namib; Schachtschneider and February, 2010). Additionally, a series of large ephemeral rivers cross the central and northern regions of Namib Desert from east to west. Wildlife depend on the water and vegetation resources in these ephemeral rivers (Jacobson and Jacobson, 2013). Surface flows in this region only occur during significant rainfall events within the catchment and rapidly conclude after rainfall ends due to the large evaporative losses found in the Namib Desert (i.e., evaporation rates reaching 200 times the mean annual rainfall in some areas; Fig. 3; Lancaster et al., 1984).

Permanent flowing rivers occur in the Namib on Namibia's northern and southern borders—the Kunene River to the north and the Orange River to the south—which harbor additional biodiversity not typically associated with deserts. For instance, the Kunene River is home to Nile crocodiles (*Crocodylus niloticus*) and Nile soft-shelled terrapins (*Trionyx triunguis*).

Namib Desert Biodiversity

Much of the published research on the biodiversity, climate, and geology of the Namib Desert has been conducted by researchers and affiliated scientists at the Gobabeb Research and Training Centre located at the ecotone in which the Namib Sand Sea meets the

Fig. 2 The mountainous terrain adjacent to the Hoanib River in the northern Namib Desert. Courtesy Emsie Verway.

Fig. 3 The Hoanib River in flood. Courtesy Emsie Verway.

central Namib gravel plains (Henschel and Lancaster, 2013). Because of this research station, much is known about this region's unique smaller fauna, including the Namaqua chameleon (*Chamaeleo namaquensis*; Fig. 4), the web-footed gecko (*Pachydactylus ran-gei*), the shovel-snouted lizard (*Meroles anchietae*), and the sidewinder or Peringuey's adder (*Bitis peringueyi*). Many of these species

Fig. 4 A Namaqua chameleon. Courtesy Emsie Verway.

or their prey, such as tenebrionid beetles, have adapted to collect fog water from the edges of the Namib's sand dunes, which are among the tallest linear dunes in the world (Bristow et al., 2000).

Further north of the Namib Sand Sea and Namib gravel plains, biologists have mainly focused on the large mammal and plant communities concentrated in the Namib's ephemeral river systems. Among the unique plants found in this region, the continuously-growing broadleaved evergreen welwitschia (*Welwitschia mirabilis*) is an endemic gymnosperm (Henschel et al., 2019). Individuals of this species are among the world's oldest living plants, with ages estimated up to 3000 years (Bornman et al., 1972). The northern Namib Desert is unique in that it is home to three desert-adapted megaherbivores (Viljoen, 1987), including the African elephant (*Loxodonta africana*), the Angolan giraffe (*Giraffa giraffa angolensis*; Fig. 5), and the world's largest population of free-ranging black rhinoceros (*Diceros bicornis*). Smaller herbivores include Hartmann's mountain zebra (*Equus zebra hartmannae*), greater kudu (*Tragelaphus strepsiceros*), gemsbok or oryx (*Oryx gazella*), springbok (*Antidorcas marsupialis*), and steenbok (*Raphicerus campestris*). Low densities of pastoralists and their livestock live among several large carnivores in this region (Lavery et al., 2019), including the African lion (*Panthera leo*), leopard (*Panthera pardus*), cheetah (*Acinonyx jubatus*), caracal (*Caracal caracal*), spotted hyena (*Crocuta crocuta*), brown hyena (*Hyaena brunnea*), and black-backed jackal (*Canis mesomelas*). Other common species

Fig. 5 An Angolan giraffe in the northern Namib Desert. Courtesy Emsie Verway.

include the common ostrich (*Struthio camelus*) and Chacma baboon (*Papio ursinus*). While charismatic large mammals are relatively well-studied in the Namib Desert, little is known about many other species. Among those understudied are one of the most diverse and successful groups of mammals in deserts—bats (Carpenter, 1969).

Bat Natural History and Species Richness Patterns

Worldwide, bats comprise more than 20% of mammals (Simmons, 2006). The majority of bat species are insectivorous and play a major role in both the regulation of nocturnal insects and the movement of nutrients across landscapes, particularly from stream corridors to roost sites (Pierson, 1998). Relative to their body size, bats travel large distances (i.e., several kilometers per night) and consume vast quantities of insects (i.e., up to 100% of their body weight each night) (Kunz, 1982; Rainey et al., 1992). Despite their recognized importance in community ecology, many aspects of their basic biology, including interspecific interactions with closely and distantly related taxa, remain unknown due to the difficulties of studying nocturnal, volant organisms. Additionally, bats generally do not fit the demographic and reproductive trends for mammals of similar sizes. Most species give birth to only one pup a year and lead relatively long lives, while maintaining a high survival rate past the first year of life (Findley, 1993; Adams, 2003). From a conservation perspective, the longevity and low fecundity rates of bats should make their research a priority comparable to large mammals.

Across the globe, bat diversity is maximized in warm, wet environments and declines as temperature and water availability decrease (McCain, 2007). Bat species richness in southern Africa generally decreases as one moves from the more mesic eastern savannas to the arid western deserts (Andrews and O'Brien, 2000; Schoeman et al., 2013; Cooper-Bohannon et al., 2016; Herkt et al., 2016; Monadjem et al., 2018). While species richness is largely driven by aridity at the regional scale (Andrews and O'Brien, 2000), precipitation totals alone do not explain patterns in bat species richness in arid and semi-arid ecosystems, illustrating the need for ground-validation of species distribution models (Rebelo and Jones, 2010). In southern Africa, species richness drops to as low as four resident bat species in the Kalahari Desert, but rises to at least 11 resident species to the northwest in the more arid Namib Desert (Fig. 6). Monadjem et al. (2018) attribute this to greater availability of roosting sites (i.e., more abundant cliffs and caves) and habitat heterogeneity in the Namib Desert. Given its long history of aridity, bats found in the Namib Desert may show sufficient adaptations to water stress and thus species richness may depend more on other features found in the local environment (e.g., roost availability, habitat heterogeneity, elevational gradients). Indeed, at least one species of insectivorous bat can survive for 72 days without water in the Namib Desert (Neuweiler, 2000).

The natural history and ecology of many African bats remains poorly understood as large parts of Africa lack survey data (Guyton and Brook, 2015). Under these circumstances, discriminating knowledge gaps from true species absences is extremely challenging and impedes conservation efforts (Racey, 2013). To contribute to addressing these gaps, I sampled bat communities in the northern Namib Desert above bodies of water, where desert bats typically concentrate in higher numbers for access to water and/or food (Adams and Thibault, 2006). From 27 February 2016 to 4 April 2017, I used a combination of invasive (i.e., mist netting) and noninvasive methods (i.e., acoustic detectors) to identify species presence and activity levels. To the best of my knowledge, this research is the first exhaustive study on bats in the region beyond a few short-term museum collection trips (e.g., Shortridge, 1934). My goal was to not only document the diversity of bats in this region, but also understand how various biotic and abiotic factors contribute to their distributions.

Study Area

My research took place in the northern Namib Desert, specifically the Kunene Region of Namibia, with sites in or adjacent to Skelton Coast National Park (Fig. 7). I regularly surveyed bats over 25 permanent bodies of water located within the catchments of the Hoanib, Uniab, Koigab, and Huab Rivers—4 of the 12 major ephemeral rivers of Namibia (Jacobson et al., 1995). In total, my study area encompassed more than 24,000 km². While mean annual rainfall exceeds 300 mm in the eastern headwater regions within these catchments, it declines to near zero in the west where the rivers meet the Atlantic Ocean (Berger, 1997; Jacobson and Jacobson, 2013). The eastern and western edges of my particular study area receive on average approximately 100 and 30 mm of annual precipitation, respectively. Permanent surface water sources in this region consist of natural springs, artificial pools constructed for wildlife and/or livestock use, and short (≤ 3 km) running water stretches. During the wet season (January to April) rivers sustain aboveground flows for on average less than 20 days per year (Jacobson et al., 1995; Leggett et al., 2001; Jacobson and Jacobson, 2013).

Bats of the Northern Namib Desert

Using a combination of mist netting and acoustic sampling, I detected 19 species of bats in the northern Namib Desert over permanent bodies of water (unpublished data). This included two species in the family Pteropodidae—the Angolan epauletted fruit bat (*Epomophorus angolensis*) and the African straw-colored fruit bat (*Eidolon helvum*)—which feed on the fruits of trees in this region. These species are the largest that I encountered (weighing ~ 90 and 200 g, respectively) and are characterized by dog-like faces

Fig. 6 Species richness patterns of bats in Africa based on potential distributions derived from niche modeling. Species richness declines east to west in southern Africa and is low in other arid zones of the continent, including the Sahara Desert in the north. The insert focuses on the species richness in arid southern Africa and highlights the spatial variability of bat diversity in this region. Reproduced with permission from Monadjem, A., Conenna, I., Taylor, P.J. and Schoeman, C. (2018). Species richness patterns and functional traits of the bat fauna of arid southern Africa. *Hystrix* **29**, 19–24.

and relatively large eyes. They do not echolocate to find their food, but instead orient by vision and sense of smell. While the Angolan epauletted fruit bat is endemic to the northern Namib Desert, the African straw-colored fruit bat is transient, only appearing during the early winter months (i.e., May and June) of my sampling period when strong winds blew in from the east.

The remaining 17 species that I detected were insectivorous species (Fig. 8). Two free-tailed bats (family Molossidae)—Roberts’s flat-headed bat (*Sauromys petrophilus*) and the Egyptian free-tailed bat (*Tadarida aegyptiaca*)—were the species most commonly captured in mist nets. Many free-tailed bats are characterized by a wrinkled upper lip, which gives them a bulldog-like appearance, and all have a tail that extends beyond the tail membrane (Monadjem et al., 2010). Long and pointed wings provide these species with swift, agile flight. They are open-air foragers with low echolocation frequencies sometimes audible to humans (i.e., any frequency ≥ 20 kHz). Roberts’s flat-headed bat has a flattened skull, allowing it to roost in narrow cracks and under slabs of exfoliating rock in small colonies (~ 10 individuals). The slightly larger Egyptian free-tailed bat similarly roosts under exfoliating rocks and crevices, but can also be found in caves, hollow trees, behind the bark of dead trees, and in buildings where they roost in larger colonies (dozens to hundreds). Both free-tailed species are permanent residents of the northern Namib Desert as they were captured and acoustically detected year-round, but at higher rates during the wet season when their insect prey is presumably more abundant.

Most of the species I captured or detected were in the Vespertilionidae family, also known as plain-faced or evening bats. These bats are characterized by a long tail fully enclosed within the tail membrane, plain noses without additional flaps of skin, and a conspicuous tragus, or specialized flap of skin in the ears of many insectivorous bats of variable shape and size. I captured two Vespertilionidae species that are endemic to the Namib Desert—the Angolan wing-gland bat (*Cistugo seabrae*) and the Namibian long-eared bat (*Laephotis namibensis*). The former was among the smallest species that I captured, weighing on average 3.5 g. Very little is known about the ecology of these species, but both are clutter-edge foragers who feed on insects in more vegetated environments. I physically captured and recorded five other species in the Vespertilionidae family that were all clutter-edge foragers, including the long-tailed serotine (*Eptesicus hottentotus*), the Cape serotine (*Neoromicia capensis*), the Zulu serotine (*Neoromicia zuluensis*), Schlieffen’s twilight bat (*Nycticeinops schlieffeni*), and the yellow-bellied house bat (*Scotophilus dinganii*). The long-tailed serotine roosts in small groups of two to four individuals in caves and rock crevices. The Cape serotine and Schlieffen’s

Fig. 7 Map of the 2016–2017 study area from which bats were sampled.

twilight bat roost under the bark of trees and under the roofs of houses, which explains why they were only detected at springs around human settlements (e.g., Sesfontein) in the northern Namib Desert. The Cape serotine is considered to be one of the most widespread species of bats in southern Africa (Monadjem et al., 2010). Little is known about the roosting behaviors of the Zulu serotine. The presence of the yellow-bellied house bat is often tied to the availability of trees as their roosts include tree hollows in addition to roofs of houses.

The remaining eight species physically captured or acoustically detected were cave-dwelling bats of the families Rhinolophidae, Hipposideridae, Nycteridae, and Miniopteridae. I physically captured two species of Miniopteridae—the greater long-fingered bat (*Miniopterus inflatus*) and the Natal long-fingered bat (*Miniopterus natalensis*). Species in the Miniopteridae family are characterized by an elongated bone toward the edge of their wings (i.e., the second phalanx of the third digit) that allows their wing to “bend” back onto itself, providing them with the common name of “bent-wing bats.” The long, narrow wings of these species help them efficiently fly in open areas, but they forage more in vegetated environments (i.e., clutter-edge foragers).

Unlike the other insectivorous bats described above, species in the families Nycteridae, Hipposideridae, and Rhinolophidae all produce echolocation pulses emitted through their noses (rather than through their mouths) to locate their prey and avoid obstacles at night. I captured and recorded one species of the family Nycteridae—the Egyptian slit-faced bat (*Nycteris thebaica*). The genus *Nycteris* is characterized by a T-shaped tail (i.e., the last vertebra of the tail is bifurcated at its tip). This species is a clutter forager with short, rounded wings that assist in slow, maneuverable flight. It flies low above the ground listening for prey on the surface

Fig. 8 A sample of the diversity of insectivorous bats captured in the northern Namib Desert.

with its large ears. Besides caves, the Egyptian slit-faced bat has also been found roosting in aardvark (*Orycteropus afer*) burrows, culverts under roads, and the trunks of large trees (Monadjem et al., 2010). Species in the family Nycteridae are often called “whispering bats” due to their soft, low-intensity, multi-harmonic echolocation calls, which prove difficult to record with acoustic detectors unless positioned at short distances.

I physically captured one species in the family Hipposideridae—Sundevall’s leaf-nosed bat (*Hipposideros coffer*)—but also infrequently recorded the striped leaf-nosed bat (*Hipposideros vittatus*). Both species have characteristic half-moon shaped noseleaves and highly maneuverable, broad wings. While the clutter-edge forager striped leaf-nosed bat is dependent on caves for roosting and breeding, the clutter forager Sundevall’s leaf-nosed bat utilizes sinkholes and cavities, including mines and culverts, in addition to caves for roosting habitats. Sundevall’s leaf-nosed bat had the highest frequency echolocation call recorded in the northern Namib Desert (i.e., a peak frequency of ~140 kHz).

Lastly, I recorded three species in the Rhinolophidae family—the Damara horseshoe bat (*Rhinolophus damarensis*), Dent’s horseshoe bat (*Rhinolophus denti*), and Rüppell’s horseshoe bat (*Rhinolophus fumigatus*). All three species are clutter foragers with broad wings and maneuverable flight. They have intricate noseleaves and produce distinct constant frequency echolocation calls. In addition to caves, these species roost in mines, road culverts, cavities and crevices in rock outcrops, and under thatched roofs. While these species are difficult to capture in mist nets (I only physically captured Rüppell’s horseshoe bat), they were frequently recorded over the bodies of water in my study area. The Damara horseshoe bat (*Rhinolophus damarensis*) is a near-endemic species to the Namib Desert.

Key Threats to Bats of the Northern Namib Desert

To assess threats to bats in this region, a translator and I conducted 86 semi-structured interviews of pastoralists across three conservancies in the northern Namib Desert. Among questions to assess for wildlife value orientations and the types and frequencies of interactions with wildlife in general (Lavery et al., 2019), I also inquired about bat presence and behaviors (unpublished data). Preliminary analyses of these data suggest that many respondents were aware of bats in their vicinity, but could not necessarily identify them in photographs. Interviews also indicated that bats are very infrequently killed in the region and are not consumed as food by local ethnic groups (i.e. Damara, Herero, Himba, and Riemvasmaker).

Our knowledge on the distributions and habitat requirements of bats in the Namib Desert is very restricted. Only three of the 19 species I detected in this study—the African straw-colored fruit bat, the Angolan epauletted fruit bat, and the striped leaf-nosed bat—are classified as near-threatened by the IUCN Red List of Threatened Species. The remaining species are classified as least concern although many aspects of their natural history remain unknown. It is believed that many Namib Desert bats live in rock crevices or caves and thus are unlikely to be affected by local pastoralists (Monadjem et al., 2010). Therefore, the greatest threats to bat conservation in the region likely include those related to water quality and availability (Fig. 9). The loss of or

Fig. 9 Kuidas Spring along the Huab River in the northern Namib Desert.

degradation to open water sources, such as a reduction in water quality, may be caused by increased use of these habitats by humans or livestock. Mining activity not only destroys potential bat roosting habitats, but can also pollute water sources with heavy metals that may bioaccumulate in bats (Korine et al., 2016). Given the extreme variation in annual precipitation in the Namib Desert, more research is needed to (1) confirm which species reside in the region or migrate through, (2) detail relative population trends or activity levels in this region over space and time, and (3) document the extent of bat distributions over the entirety of the Namib Desert.

Additional Threats to Namib Desert Biodiversity

As in any desert ecosystem, a major threat to people, livestock, and wildlife in the Namib Desert includes a drop in the water table due to groundwater extraction within ephemeral river catchments. The extensive water demands for mining operations, particularly for uranium, often fuels this problem (Lovegrove, 1993; Jacobson and Jacobson, 2013). Where water is used, roads, pipelines, and powerlines are constructed to access the source, damaging local habitat. The creation of desalination plants on the Atlantic coast to meet domestic and industrial water needs may reduce the current demand for groundwater extraction, but the energy requirements associated with desalination has limited its application in Namibia (Jacobson and Jacobson, 2013).

Although much of the western Namib Desert is protected and thus incurs little to no impacts of human settlements (Seeley and Pallett, 2008), off-road driving is a major threat to this region. The greatest impact of off-road driving occurs on the gravel plains where depressions left by vehicles can remain for more than 40 years. Lichens are especially sensitive to off-road driving as they grow extremely slowly and cannot repair damage quickly. This threat is largely caused by mining company vehicles on prospecting expeditions (Lovegrove, 1993), but self-drive tourists are increasingly contributing to this problem.

Climate change may exacerbate these problems as temperatures are predicted to increase and precipitation to decrease over the next 100 years (de Wit and Stankiewicz, 2006; Dai, 2011). With less rainfall, off-road tracks are less likely to be washed away and the water table will likely continue to lower. Population declines along the northern range limit of the quiver tree (*Aloidendron dichotomum*) in the Namib Desert suggests regional warming and drying has already begun, as this species is relatively tolerant of drought and climatic variation (Foden et al., 2007). While temperature increases combined with decreased rainfall should reduce any downstream flow of the Namib's ephemeral rivers, runoff patterns are also expected to change with predicted increases in rainfall intensity and potential responses of catchment vegetation (New et al., 2006; Jacobson and Jacobson, 2013).

History, Land Use, and Conservation Opportunities

Despite its isolation and low human population densities, wildlife populations in the northern Namib Desert declined over the early and mid-1900s due to expanding human settlements, war, intensive hunting and poaching, and drought (Viljoen, 1987;

Leggett et al., 2003). Since the early 1980s, conservation efforts have focused on northwestern Namibia, where wildlife populations have stabilized or increased since the country's independence in 1990 (Scanlon and Kull, 2009). Unlike most countries, Namibia's constitution explicitly safeguards biological diversity and essential ecological processes (Barnard et al., 1998). Wildlife populations have increased due to effective law enforcement, the creation of communal conservancies, and the shift in natural resource ownership from government entities to property owners. While much of the western Namib Desert is protected as national parks, parts of the coast are still actively mined with restricted public access.

The western reaches of the northern Namib Desert make up Skeleton Coast Park, while the desert to the east is primarily comprised of communal conservancies (i.e., land areas collectively managed by residents who have agreed to conserve and share their natural resources in a sustainable and economically beneficial manner; Shaw and Marker, 2010). Only established in Namibia after the 1996 Nature Conservation Amendment Act, conservancies are home to many ethnic groups (Laverty et al., 2019). Local pastoralists in the area rely on livestock for income, although ecotourism and trophy hunting are also increasingly important (Bandyopadhyay et al., 2004; Lindsey et al., 2007). Except for a veterinary fence built to restrict foot-and-mouth disease transfer, these conservancies are mostly unfenced, which permits free movement of wildlife and livestock in the desert (Rust and Marker, 2014). As in other areas in southern Africa using community-based natural resource management (CBNRM), these conservancies allow both consumptive and non-consumptive uses of wildlife, and have devolved management responsibility to local people (Van Schalkwyk et al., 2010).

To assess local conservation challenges and highlight potential means to address any problems, I analyzed additional data from the 86 semi-structured interviews of pastoralists described earlier (Laverty et al., 2019). Most respondents reported challenges related to subsistence needs, including human and livestock safety as well as reliable access to water. Over 90% of interviews mentioned carnivores killing livestock as a primary problem to living among wildlife. The most commonly reported suggestions to reduce conflicts with wildlife addressed this issue. Recommendations involved moving or reducing local predator populations, but not eliminating them entirely. Nearly 25% of interviews favored fencing predators within the conservancies, but away from human settlements. This would not only allow residents to retain the benefits that predators bring as tourist attractions, but would also provide pastoralists and their children the chance to still encounter these species. Using semi-structured interviews allows not only an assessment of the greatest perceived human-wildlife challenges in a region, but also the identification of potential management solutions most likely to be supported by local communities.

Conclusions

The Namib Desert is one of the world's oldest deserts, known for its geological variability and diverse arid-adapted biota. The northern reaches of the desert are home to African elephants, black rhinoceroses, and Angolan giraffes, which are some of the world's largest terrestrial mammals. It is also home to variety of small, understudied mammals, including at least 19 species of bats. My research in the northern Namib Desert highlighted the importance of waterholes as resources for this diverse community of desert-dwelling bats. Many aspects of the natural history of bats in this region remain unknown and require further investigation, but Namib Desert bat populations do not appear to be particularly threatened by humans at this time. Local pastoralist communities instead are largely concerned about carnivores threatening human and livestock wellbeing in addition to securing reliable access to water. Semi-structured interviews suggested that pastoralists generally tolerate living among local wildlife, but management of predator populations in particular may be necessary for long-term human-wildlife coexistence.

Abstract

This article provides a comprehensive introduction to desert ecosystems and the many challenges their conservation poses to human societies. The first section focuses on highlighting the unique biodiversity capable to cope with the extreme environmental conditions that characterize deserts. We then briefly review current desert conservation policy and its effectiveness, describing some of the frameworks in place to protect desert ecosystems and the millions of people that depend upon them. The third section identifies the main anthropogenic threats to desert wildlife and discusses how climate change may substantially alter the functioning of these ecosystems. The final section details current and potential conservation strategies that may help secure this unique biodiversity in the near future.

What Are Deserts?

Deserts are a type of dryland, which are ecosystems characterized by a deficit in moisture: year on year, they lose more water via evaporation than they receive from rainfall (Table 1). In fact, annual rainfall provides on average <250 mm of water in deserts. Additionally, these ecosystems often experience extreme day and night temperatures, averaging 38 °C in the daytime and falling to −3.9 °C overnight. Deserts can be found all over the world: the world's largest desert is the polar desert of the Antarctic, which stretches over 14.2 million square kilometers. The largest hot desert is the Sahara Desert, which covers over 9 million square kilometers in Africa. Both the lowest and highest temperatures ever recorded on Earth were found in deserts: a record low of −89.2 °C has been measured in Antarctica, whereas a record high of 58 °C has been documented in the Sahara.

Deserts occur in a range of different climatic zones: subtropical, cool winter, cool coastal, and polar deserts (Fig. 1). Sub-tropical deserts, such as the Sahara, Mojave and Sonoran Deserts, are the hottest, characterized by high temperatures and warm soils. These deserts are usually found in sandy or rocky landscapes. Cool winter deserts have long dry summers and cold winters with low rainfall or snowfall. They are shielded from precipitation by neighboring high mountain ranges, such as the Himalayas (next to the Gobi) and the Andes (next to the Patagonian Desert). Coastal deserts, such as the Namib Desert and the Atacama, receive moisture from coastal fog blown in from the sea. In these deserts, plants have evolved adaptations to soak up the air moisture while a number of herbivorous animals primarily source their water from eating plants. Polar deserts, such as those found in Antarctica, receive very little precipitation and remain at very low temperatures all year round: there, the average temperature is between −10 °C and −60 °C.

Key ecological characteristics of deserts include their low productivity, sparse vegetation and minimal aquatic features. Trees are often absent, and shrubs provide incomplete ground cover. Although rainfall is generally the main limiting factor for ecosystem processes characterizing deserts, the availability of important nutrients such as nitrogen and phosphorus can also be low, further constraining primary productivity (Hadley and Szarek, 1981). Desert flora and fauna tend to be highly specialized, as the extreme conditions mean that only highly adapted species can withstand the characteristic high temperatures and long drought episodes. Some of these unique desert species can be important ecosystem engineers. For example, large shrubs and occasionally trees can create a unique shaded microhabitat for other species under which to grow. Termites aid the process of decomposition and allow

Table 1 Defining drylands by aridity (UNEP-WCMC, 2011). The aridity index is defined as the average annual precipitation divided by potential evapotranspiration

Aridity index	Level of aridity	Ecosystem	Percentage of global land AREA (%)	Locations
0.00–0.03	Hyper-arid	Desert	6.6	Sahara, Gobi, Atacama deserts
0.03–0.20	Arid	Semidesert	10.6	Australian and United States deserts
0.20–0.50	Semiarid	Grassland	15.2	Occur on outskirts of deserts
0.50–0.65	Dry-sub-humid	Rangelands	8.7	Occur on outskirts of grasslands

Fig. 1 World map providing examples of desert adapted species found in subtropical, cool winter and cool coastal deserts.

water to infiltrate the dry soil via the creation of micropores. Larger herbivores also control habitat structure by grazing and supporting seed dispersal, allowing other species to thrive in these seemingly hostile environments.

The main challenge faced by plants in deserts is obtaining and retaining water for photosynthesis. They generally limit water loss by reducing the size and number of stomata and by having waxy coatings and tiny leaves. But some plants (Crassulacean Acid Metabolism (CAM) plants) are also able to capture the carbon dioxide needed for photosynthesis by opening their stomata during the night, when temperatures are low and transpiration rates are slower, thereby reducing water loss. Other adaptations seen in desert plants include reduced leaf networks, such as cacti, as well as dormancy in seeds and delayed germination, which enable these plants to only reproduce and grow during the wetter periods of the year.

Lower densities of resources due to low productivity in deserts means animals often occur at lower densities and have much larger ranges than in other biomes (see e.g., [Belbachir et al., 2015](#)). Many desert animals gain enough moisture from their diet to survive the arid conditions, whereas some are able to make the most of sporadic water sources by drinking and storing large quantities in fat deposits (e.g., camels (*Camelus dromedarius*)). As well as finding enough water, limiting water loss is also an issue for animals in deserts as thermoregulation is often controlled by evaporative heat loss, like sweating or panting. In extreme temperatures, maintaining a safe body temperature is vital because hyper- or hypothermia can lead to organ failure and death. To avoid overheating, and therefore minimize the need to thermoregulate by evaporation, behavioral adaptations such as burrowing, nocturnal activity and shade-seeking are often seen in desert animals. Physiological adaptations such as long limbs or large ears can also reduce the need for evaporative cooling by providing larger body surface areas from which heat can be dissipated via radiation and convection. Some highly specialized mammals including camels and other ungulates can withstand large fluctuations in body temperature throughout the day: being able to modulate their body temperature to such an extent allow them to lessen the difference between body and air temperatures, thereby reducing the need for evaporative heat regulation ([Fuller et al., 2014](#)). Other unusual adaptations of desert wildlife include the ability to obtain drinking water from high-salt content water by secreting excess salt via salt glands, like in several species of iguana and birds. For a more in-depth introduction to desert environments, specially adapted species and the biology of the habitat, see *The Biology of Deserts – David Ward (2009)*.

Conserving and Protecting Deserts

Deserts are delicate and unique ecosystems with enormous value to wildlife and people. They are widely distributed—covering 17% of Earth's land mass—and host 25% of terrestrial vertebrate species, making them one of the richest biomes for terrestrial vertebrates ([Mace et al., 2005](#); [Millennium Ecosystem Assessment, 2005](#)). They are also rich in endemics as well as being home to some of the most endangered species in the world ([Davies et al., 2012](#)). Some of the species found in deserts are both evolutionarily and ecologically unique, giving them incredibly high conservation value because they represent a significant amount of unique evolutionary history (see www.edgeofexistence.org). However, the low productivity of deserts means that they tend to be overlooked in terms of

their conservation importance. For instance, the Saharan nations cover 43% of Africa's land mass yet only received 12% of Global Environment Facility funding allocated to Africa between 1991 and 2009 (Durant et al., 2012).

Deserts moreover support some of the most marginalized human populations in the world and provide key ecosystem services to 6% of the world's human population, many of whom are at immediate threat from rapid environmental change (Middleton et al., 2011). Traditionally, people in deserts live in hunter-gatherer communities or are pastoralists, surviving on the resources the environment provides. Often this requires a nomadic lifestyle with no permanent home base, which means that these people regularly cover large distances to secure access to water, food and material. Mobility is thus key for these communities to benefit from the ecosystem services provided by deserts.

Protecting deserts and the people in them is achieved through a number of policy frameworks. For example, the protection of deserts is a central tenant of the United Nations Convention to Combat Desertification (UNCCD). As indicated by its name, the convention primarily focuses on desertification, a type of land degradation in which a relatively dry area of land becomes increasingly arid, resulting in a loss of water bodies, vegetation and wildlife as well as widespread poverty. Desertification is thought to affect as much as one-sixth of the world's population, 70% of all drylands, and one-quarter of the total land area of the world. The current 2018–30 UNCCD framework aims to “*avoid, minimise and reverse desertification and land degradation and mitigate the effects of drought*” (<https://www.unccd.int/>). However, the UNCCD's visibility and capacity are presently relatively low, and the convention has received criticism for its lack of action (Conliffe, 2011; Tollefson and Gilbert, 2012). Together with the low level of funding targeting desert regions, achieving the 2018–30 UNCCD targets is therefore expected to be challenging. Interestingly, desertification has also been recognized as a pressing issue by the United Nations' Sustainable Development Goals (SDGs; <https://sustainabledevelopment.un.org/>), which broadly aim to encourage all nations to tackle poverty and protect the natural world into the future. SDG 15 of the 2030 Agenda, in particular, aims to “*protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss*.” Such a recognition could help catalyze conservation activities in deserts in the years to come.

The Convention on Biological Diversity (CBD) is another key policy framework for desert conservation, through its work on developing and supporting a comprehensive, effectively managed and sustainably funded global network of protected areas. Protected areas currently cover 13% of the world's dryland areas and can prevent desertification by protecting plant cover (UNEP-WCMC and IUCN, 2016; Dudley et al., 2015). However, protected area coverage is uneven among different types of drylands (Davies et al., 2012), and even in deserts affording good levels of protection (such as the Sahara), conservation priority areas have been thought to be inadequately captured by the current protected area network (Brito et al., 2016).

Other important policy instruments to safeguard deserts include regional treaties and acts, such as the Protocol on Environmental Protection to the Antarctic Treaty (The Madrid Protocol). Adopted in 1991, this protocol secured the designation of Antarctica as a natural reserve and the indefinite prohibition of mining in the area. Another interesting example is the California Desert Protection Acts (1994; 2010; 2017), which have explicitly acknowledged the importance of balancing the protection of the United States of America's (USA) unique desert landscapes for nature conservancy, recreation opportunities and development of renewable energy.

Principal Anthropogenic Threats to Desert Ecosystems

Human actions have a substantial impact on desert environments: in the Sahara-Sahel region, for example, anthropogenic actions are currently thought to represent the biggest threat to desert biodiversity (Brito et al., 2014). Until recently, illegal hunting of wildlife was the primary driver of extinction, but now resource extraction and habitat degradation due to increasing agricultural activities are becoming just as important (Newby et al., 2016). Overgrazing by livestock, unsustainable use of natural resources and conversion of natural habitat into pasture cause landscape fragmentation and lead to the destruction of valuable microhabitats. In addition, overexploitation of water resources reduces water quality, through, for example, fecal contamination and excessive eutrophication, and can lead to increased human-animal conflicts (Brito et al., 2014).

Despite the arid conditions, farming can occur in deserts. Often farmers will own livestock such as sheep, goats, cattle and camels; in many situations, farmers will have to move long distances to find suitable grazing areas and water sources for their livestock. Farming in deserts can yet impact ecosystem dynamics and cause problems for the uniquely adapted wildlife. In the Gobi Desert and throughout Patagonia and the Monte, livestock grazing is thought to affect the functioning of desert ecosystems by reducing resources for wild animals and by changing the accumulation of water in the soil, thereby promoting desertification (Ekernas et al., 2017; Bisigato and Laphitz, 2009). In addition, encroachment of agriculture and human settlement, perhaps in part due to the greening of deserts (see below), increases opportunities for human and wildlife interactions. This represents another substantial threat, which is on the increase in some deserts and is negatively affecting conservation and wildlife recovery (Newby et al., 2016). Higher levels of encroachment and human-wildlife conflicts have led to various calls for large-scale fencing. These calls have, however, been met with a certain amount of skepticism: in dryland ecosystems, animals and people indeed rely on wide-ranging mobility to access unpredictable and sporadic resources, and fences could prevent access to these resources (Durant et al., 2015). Dryland reserves often do not cover the entire extent of an animal's range, or do not include both dry or wet season ranges for migratory species (Fynn and Bonyongo, 2011). Fencing such reserves could thus disrupt access to widespread resources and seasonal migrations.

Increased human activities in deserts impact natural resource supplies, especially of water, and can increase the incidence of bushfires and disease transmissions (Newby et al., 2016). Over 70% of global water loss over recent decades is concentrated in five countries, all of which contain desert ecosystems within their national boundaries. There, water loss is thought to be primarily caused by anthropogenic actions, such as water course diversion (Pekel et al., 2016). Creating artificial water sources can lead to an unnatural spatial concentration of wildlife and livestock; these can then favor disease spread and lead to greater levels of human-wildlife conflicts, both of which ultimately potentially generating further biodiversity loss (Fig. 2; Owen et al., 2015).

Extractive activities (oil, gas, minerals) are also becoming more common in desert environments, leading among other things to the expansion of the local road networks and the construction of other new infrastructures. These developments tend to be associated with the destruction of rare habitats and frequently endanger threatened wildlife, such as the desert tortoise in the Mojave (Boarman and Sazaki, 2006) and the last wild addax population (*Addax nasomaculatus*) in Niger (Duncan et al., 2014). Rising global demand for minerals, in particular, has been causing an increase in mining activities in deserts around the world, contributing to environmental degradation in these ecosystems (Brito et al., 2014).

More roads in deserts also means that remote areas previously known to act as refuges are becoming more accessible to poachers. A number of studies have now established that roads are a significant problem for desert wildlife around the world: in the Gobi Desert for example, roads and trainlines to mining sites are dividing habitats and obstructing wide-ranging migrations (Ito et al., 2013). Road collisions are one of the main threats to Iranian desert cat populations such as the Asiatic cheetah (*Acinonyx jubatus venaticus*) and sand cat (*Felis margarita*) (Farhadinia et al., 2017; Ghadirian et al., 2016).

Drylands are primarily found in the most conflict-prone regions of the world, due in part to environmental degradation adversely affecting political and economic stability on many scales (Middleton et al., 2011). Sensitivity to conflict, together with poor governance and high corruption levels that characterize some of the countries hosting major deserts, has further contributed to desert biodiversity loss (Brito et al., 2018). In Niger, for example, oil companies and the army both ignored environmental and security regulations protecting the addax, which led to a significant decline in population size, an environmental crime that was left unpunished (Brito et al., 2018). Other reports of political corruption in Niger means that funds meant for conservation and combatting desertification have often been diverted to other uses (Usman and Adefalu, 2010). In many countries hosting desert ecosystems, conflict and political instability have promoted the circulation of firearms; used in combination with motorized vehicles, this drastic change from traditional hunting approaches can lead to unsustainable levels of offtake (Newby et al., 2016). Similarly, the use of firearms and associated danger to public safety has led to a reduced level of protection for both wildlife and the landscape, even in legally protected areas (Brito et al., 2018). The clear association between the population decline in elephants (*Loxodonta africana*) and Dorcas gazelle (*Gazella dorcas*) and the increased level of human conflicts in the Sahara-Sahel region is an example of how political instability can influence conservation outcomes (Brito et al., 2018). Similarly, illegal killings of animals were reported to accelerate 2–3 years after armed conflicts began in Libya and Mali, suggesting the organized crime and conflict had a negative effect on species conservation (Brito et al., 2018).

Table 2 describes the decline of the 14 large vertebrates typical of the Sahara-Sahel region, many of which are endemic to that part of the world. Four are now extinct in the wild and the majority have been lost from more than 90% of their Saharan range—all are now on the brink of extinction due to the combined impact of anthropogenic actions.

Deserts and Climate Change

Anthropogenic climate change is affecting biodiversity worldwide and deserts are among the places where climate change is happening at the highest speed (Loarie et al., 2009). In fact, many would argue that climate change is the dominant driver of

Fig. 2 Artificial waterpoint, and the subsequent damage to the surrounding environment, as seen from space. Image captured in the Ouadi Rime-Ouadi Achim Faunal Reserve, Chad, and obtained from Bing Maps (Microsoft 2014).

Table 2 Endangered megafauna of the Sahara-Sahel and their associated range loss.

Species	Current status (IUCN)	Range loss in Sahara (%)
Bubal hartebeest (<i>Alcelaphus buselaphus buselaphus</i>)	EX	100
Scimitar-horned oryx (<i>Oryx dammah</i>)	EW	100
Addax (<i>Addax nasomaculatus</i>)	CE	99
Dama gazelle (<i>Nanger dama</i>)	CE	99
Saharan cheetah (<i>Acinonyx jubatus hecki</i>)	CE	90
African wild dog (<i>Lycaon pictus</i>)	EN	100
Slender-horned gazelle (<i>Gazella leptoceros</i>)	EN	86
Cuvier's gazelle (<i>Gazella cuvieri</i>)	EN	66
Lion (<i>Panthera leo</i>)	VU	100
Dorcas gazelle (<i>Gazella dorcas</i>)	VU	86
Barbary sheep (<i>Ammotragus lervia</i>)	VU	77
Nubian ibex (<i>Copra nubiana</i>)	VU	10
Leopard (<i>Panthera pardus</i>)	NT	97
North African ostrich (<i>Struthio camelus camelus</i>)	LC	99.8
	(Saharan race not assessed)	

IUCN status: EX = Extinct, EW = Extinct in the wild, CE = Critically endangered, EN = Endangered, VU = Vulnerable, NT = Not threatened, LC = Least concern.

Adapted from Durant, S.M., Wachter, T., Bashir, S., Woodroffe, R., De Ornellas, P., Ransom, C., Newby, J., Abáigar, T., Abdelgadir, M., El Alqarny, H. and Baillie, J. (2014). Fiddling in biodiversity hotspots while deserts burn? Collapse of the Sahara's megafauna. *Diversity and Distributions*, **20**(1), 114–122.

biodiversity change in tundra and deserts (Millennium Ecosystem Assessment, 2005). For example, anomalous increases in rainfall have stimulated the increase of vegetation and a re-greening of the Sahel, after decades of intense drought (Fig. 3; Brandt et al., 2014). There, woody vegetation cover has increased significantly since 2000, especially in areas undisturbed by humans (Brandt et al., 2016). In North America, changes in precipitation and temperature have increased the incidence of desert wildfires. There, increased abundance of invasive grasses, such as cheatgrass (*Bromus tectorum*), has provided perfect conditions for larger, longer-lasting and wider-spread fires which can ultimately impact the viability of threatened wildlife (Abatzoglou and Kolden, 2011). In cold deserts, thinning of ice caps, thawing of permafrost and retreat of glaciers have all contributed to increased rates of desertification. Thawing of ice and snow has indeed led to the depletion of the already sparse vegetation, opening the land to rapid erosion. The subsequent depletion of natural resources, such as water availability, has had severe impacts on local communities relying on ecosystem services for their survival. In addition, climatic volatility is increasing with climate change, impacting the frequency and severity of droughts and severe snowstorms, altogether resulting in devastation of livestock (Pragya, 2009). Critically, further thawing of permafrost is expected to result in a positive feedback loop, leading to more greenhouse gases being released into the atmosphere.

As exemplified above, changes in climatic conditions are impacting the distribution and occurrence of natural resources in deserts. In many situations, increased drought intensity, duration and frequency is expected to severely impact primary productivity and the availability of water, leading to declines in herbivore abundance (Duncan et al., 2012). Both the timing and the routes of species migrations are predicted to change as a result of altered food distribution and the spatiotemporal unpredictability of water availability, which could adversely affect the dynamics of migratory ungulate populations (Duncan et al., 2012).

The changing distribution and timing of resource availability is also expected to have a detrimental effect on the people living in desert environments. The United Nations Food and Agriculture Organization (FAO) reported that particularly high proportions of the rural poor are inhabiting drylands, where climate variability and vulnerability to droughts are the main drivers of poverty. In these areas, climate-related crop failures, food shortages and poor livestock condition can all exacerbate poverty levels (Middleton et al., 2011).

Fig. 3 Satellite imagery illustrating the greening of the Sahel (imagery from Google Earth: Landsat/Copernicus, December 1988 and December 2009).

Despite this sensitivity to changing climatic conditions, deserts actually have a huge potential to contribute to climate regulation—dryland environments indeed harbor an estimated one-third of terrestrial global carbon stock and could potentially sequester even more through improved land management (Trumper et al., 2008). This means that the conservation of deserts and those species displaying unique adaptations to drought and temperature extremes is an important endeavor in a world trying to adapt to climate change. Research into adaptive techniques focused on desert species could spearhead improvements in agriculture and human health, helping to prepare our world for the challenges ahead (Durant et al., 2014).

Conservation Strategies for Maintaining Deserts in an Increasingly Human-Dominated World (Anthromes)

The uniqueness of deserts, their outstanding biodiversity and the growing threats to their survival means they are of immediate conservation concern. Identifying conservation strategies that can address the challenges posed by rapidly changing environmental conditions is vital for the maintenance of deserts and their wildlife in the future. For these remote and inaccessible areas, new technologies could enable better monitoring, provide a better knowledge base and enable faster development of adaptive solutions to the threats described above.

Satellite remote sensing, in particular, has been shown to successfully support the identification and monitoring of anthropogenic threats to desert biodiversity, such as the detection of oil exploration activities (Duncan et al., 2014) and the creation of artificial water holes (Owen et al., 2015). Open access satellite imagery from Landsat and MODIS could prove vital for the success of conservation work as extractive activities continue to penetrate further into remote desert regions. Similarly, satellite remote sensing has been a key tool for broadening our understanding of desert ecosystem dynamics under changing climatic conditions. For example, the detection of the re-greening in the Sahel (as seen in Fig. 3; Brandt et al., 2014, 2016; Dardel et al., 2014). Because satellite remote sensing has been going on for decades, the technology also has potential to directly support environmental management decision making processes by assessing long-term trends in primary productivity, forest cover, habitat heterogeneity and threat levels within the landscape (Pettorelli et al., 2014). In Chad, for example, conservationists were able to use satellite imagery to assess the suitability of a given reserve for the reintroduction of the Scimitar-horned oryx (*Oryx dammah*) (Freemantle et al., 2013).

Camera traps are another useful remote sensing technology for the management and conservation of elusive desert wildlife. This tool, which collects on-the-ground information on species distribution, has proven particularly valuable for estimating population size, as well as for deriving information on behavior, health and species interactions. Camera traps were used to show that the critically endangered Saharan cheetah (*Acinonyx jubatus hecki*) survives in the harsh desert environments at much lower density than cheetahs in savannah environments; individuals were also found to be wider-ranging and more nocturnal (Fig. 4; Belbachir et al., 2015). The ecological knowledge gained on this particular species ultimately enables the development of a better, more targeted approach to its conservation.

Adopting a wide range of new technologies for monitoring deserts is only part of the solution to designing efficient conservation strategies for these ecosystems. Another important aspect is the relevant designation and efficient management of protected areas. Large protected areas have been suggested as a useful tool to mitigate the problem of rapid climate velocity in desert biomes (Loarie et al., 2009). By increasing the size of protected areas in the desert regions, connectivity of suitable habitat can be secured more effectively, while more space enables animals to migrate more easily as the climate changes. For protected areas to work, resources and funding are needed. Sporadic funding allocated to gazetting protected areas alone does not guarantee long-term sustainable conservation outcomes (Emerton et al., 2006). Effective management strategies, long-term planning and reliable, consistent funding are needed. It has been suggested that, in developing countries, lack of financial resources or management deficiencies (e.g., lack of skilled staff) are the main limitations to the effective management of protected areas. Collaboration between protected

Fig. 4 Camera trap image of a critically endangered Saharan cheetah, captured during a survey in Algeria.

areas is another means by which more productive and sustainable conservation can be enabled, providing a mechanism for sharing best management practice (Di Minin and Toivonen, 2015).

Well-managed protected areas not only can make a difference to the conservation of resident species, but they can also be used to support other conservation initiatives such as species translocations. Translocations can be used to enhance populations of locally threatened species or reintroduce species once found in these areas; they can also be used to introduce new species in new areas in cases where future suitable conditions are expected to be found primarily outside the historic distribution range. Translocated animals can be sourced either from neighboring areas or captive breeding programs. For instance, intercontinental collaborative captive breeding programs based in the United States, Europe and the Middle East are maintaining populations of threatened Sahelo-Saharan desert species as an insurance against extinction and are supporting reintroduction projects in North Africa (Newby et al., 2016). The first reintroduction program aiming to restore a sustainable, free-ranging population of over 500 Scimitar-horned oryx (IUCN: extinct in the wild) in a protected area in Chad began in 2016. A successful birth of a calf in September 2016 is likely to be the first scimitar-horned oryx calf to be born in the wild for over 30 years. The following year, a second phase of reintroduction released more individuals into the wild in what appears to be a very promising example of reintroduction in the wild.

The translocation of animals into protected areas is however not easy. The logistics of relocating animals and suitability of the environment in which they will be hosted both need to be determined during planning. In that respect, habitat destruction and weak no-take legislation in some of the target locations are pressures to consider before translocations (Newby et al., 2016). Areas where the animals are likely to migrate to, either during natural migrations or in response to climate change and other pressures, must also be appropriate and accessible to these animals. In addition, there are significant challenges associated with captive breeding such as retaining genetic diversity, risk of adaptation to captivity, expense, and disease risk (Newby et al., 2016). These challenges mean that translocation should be seen as a last resort solution, and all efforts should be put into avoiding species become extinct in the wild in the first place.

Protected areas can also be conducive for ecotourism, another valuable method to support conservation efforts in deserts within an increasingly human-dominated world. Ecotourism is defined as “responsible travel to natural areas that conserves the environment, sustains the wellbeing of local people and involves interpretation and education” (International Ecotourism Society, 2015). Ecotourism is expected to promote conservation by developing a local wildlife-based economy and by educating both tourists and local staff about the uniqueness, wonder and conservation value of deserts. It is the fastest growing segment of tourism, generating over US \$28 billion per year for developing countries (Kirkby et al., 2011). Successful ecotourism enterprises in deserts could be used to generate new funding streams to protect biodiversity and alleviate direct and indirect pressures to the ecosystems. Desert landscapes are advantageous for ecotourism development: they are often unaltered by human activity and offer tourists a large viewing range due to the sparsely vegetated areas (Santarém and Paiva, 2015). The endangered wildlife that inhabit deserts, as well as the unique geological features and unusual vegetation, are also likely to help attract specialized tourists (Santarém and Paiva, 2015). Ecotourism has been successfully used to promote conservation in American and Australian deserts (e.g. the Grand Canyon and Simpson Desert), where protected areas attract many visitors and are subsequently sufficiently funded and well-protected (Santarém and Paiva, 2015). Admittedly, in some countries, ecotourism is currently not a viable desert conservation option: in the Sahara and Arabic deserts, for example, the current lack of facilities to accommodate people, the poor transportation facilities and the high levels of insecurity (linked to wars, corruption and kidnappings; Brito et al., 2014) result in far fewer visitors and less income from ecotourism than could be achieved. As economies in those regions rebuild, the examples from the USA and Australia should act as a reminder that healthy deserts can foster economic growth and support development.

Conclusions

We described the fascinating and exceptional properties defining desert ecosystems. The extreme abiotic conditions that characterize deserts have resulted in the evolution of highly adapted and extremely unique animals and plants. We showed that people across the world depend upon these landscapes for subsistence, for recreation and for vital ecosystem services. These areas are now under serious threat both directly, through hunting, mining, warfare and economic development, and indirectly through climate change. Conservation action needs to be stepped up in these precious environments and we have outlined the ways in which this may be achieved. Technological advances and an increase in protected area coverage can support the conservation of these ecosystems; however, these efforts will only be successful if there is a real political will to conserve these landscapes and sufficient funding is directed towards their preservation.

Abstract

The Sahara Desert is the largest warm desert on the planet, with an area comparable to that of contiguous United States. It is a key element of the African climate system. 20th-Century trends in seasonal temperature and precipitation over the African continent are analyzed from observational data to characterize the seasonal footprints of hydroclimate change. Given the prominence of agricultural economies on the continent, a seasonal perspective was considered more pertinent than the annual-average typically used in desert characterization as the latter can mask off-setting but agriculturally-sensitive seasonal hydroclimate trends. Seasonal surface air temperature (SAT) trends show that heat stress has increased in several regions, including Sudan and Northern Africa where largest SAT trends occur in the warm season—in stark contrast with the seasonal structure of climate change over northern continents where the warming is most pronounced in winter. Precipitation trends are varied but notable declining trends are found in the countries along the Gulf of Guinea, especially in the source region of Niger river in West Africa, and in the Congo river basin. Rainfall over the African Great Lakes—one of the largest freshwater repositories—has, however, increased. The Sahara Desert is shown to have expanded over the 20th century, notably southward in summer, reflecting the retreat of the northern edge of the Sahel rainfall belt. Specific mechanisms for desert expansion are investigated.

Introduction

Climate change has footprints across the planet; however, certain regions are disproportionately affected. Africa is less responsible for the occurrence than any other continent (Fields, 2005) but more vulnerable to the effects of climate change due to its high population, low adaptive capacity, and multiple converging stressors (Fields, 2005 Busby et al., 2014 Niang et al., 2014). Africa is furthermore an interesting case study for climate change due to its unique climatological features. It is the only continent that has almost equal parts in the Southern and Northern Hemispheres and thus home to a wide variety of climate zones. It consists of the Sahara Desert and Sahel in northern Africa, the Namib/Kalahari Desert in southern Africa, tropical rainforest in Equatorial Africa, and grasslands and savanna in-between. The Sahara Desert is the largest warm desert on the planet, with an area comparable to that of contiguous United States. It is bounded to the south by the Sahel—the semiarid transition zone between approximately 10° and 20°N that receives most of its rainfall in summer. Not surprisingly, the Sahara Desert appears more expansive in winter than summer in satellite imagery. The prevalence of land-surface effects, internal climate variability, and hydroclimate sensitivity to global sea surface temperatures make the continent climatically complex (Hulme et al., 2001).

Global climate change often leads to the wet regions getting wetter and the dry ones drier (Chou et al., 2013), suggesting adverse impacts on deserts. The impact on the Sahara Desert is of great importance for the proximal countries in Northern Africa as well as for remote regions through the influence of Saharan dust on sea surface temperatures (SSTs) and Atlantic hurricane activity (Evan et al., 2016). Precipitation trends have been well-studied over the Sahel region which bounds the Sahara to the south. The drying trends over Sahel have been attributed to land-surface processes, including amplification of meteorological drought from biophysical (Charney, 1975) and surface hydrologic feedbacks (Nicholson, 2000), and to the increasing concentration of greenhouse gases and aerosol loading (e.g., Held et al., 2006). Regional and global patterns of SST anomalies have also been implicated (Folland et al., 1986 Giannini et al., 2003) as have sulfate aerosols in the Northern Hemisphere through their effect on Atlantic

SSTs (Biasutti and Giannini, 2006). The 1980s Sahel drought—the most intense episode of the 20th century—has been attributed to the circulation-change associated with Indian Ocean warming (Hagos and Cook, 2008), and the drought recovery linked to higher levels of greenhouse gases in the atmosphere (Dong and Sutton, 2015). Sahel rainfall has also been linked to variability in SSTs in the North Atlantic, the Atlantic Multidecadal Oscillation (AMO) (Mohino et al., 2011 Knight et al., 2006). This oscillation has a period of 50–80 years, with the cold AMO phase coincident with extended droughts over Sahel (Kavvada et al., 2013). Causes of surface temperature variability in this region are less well-established (Collins, 2011), although an amplified warming signal has been detected over the Sahara Desert in recent decades (Cook and Vizi, 2015 Vizi and Cook, 2017). The importance of agriculture in the African economies warrants a seasonally resolved analysis of hydroclimate variability and change over the continent. This article updates the findings of Thomas and Nigam (2018) from analysis of more extended observational records, especially precipitation's. It documents the regional structure of the century-long seasonal temperature and precipitation trends over the African continent, focusing on how these trends affect the Sahara Desert boundary and expanse. The data sets and analysis methods are described in “**Datasets and Analysis Method**” section. The seasonal climatology of near-surface air temperature (SAT) and precipitation over the African continent are outlined in “**Seasonal Climatology**” section to provide context for characterization of the century-long seasonal hydroclimate trends in “**Centennial Trends in Surface Air Temperature and Precipitation**” section. Expansion of the Sahara Desert over the 20th century is discussed in “**Change in Sahara Desert Expanse over 20th Century**” section, and the summer expansion mechanisms investigated in “**Sahara's Expanse: Variation and Potential Mechanisms**” section. Concluding remarks, including sensitivity of the desert expansion rate to the analysis period follow in “**Concluding Remarks**” section.

Datasets and Analysis Method

The study focuses on centennial trends rather than multidecadal variability (a more common analysis focus) of African hydroclimate. The analysis period begins in 1920, in order to focus on the relatively stable rain gauge network period (Nicholson, 2018, personal communication). Linear trends in temperature and precipitation are computed from least-squares fitting using seasonally-averaged data. To avoid confusion given Africa's expansive footprints in both hemispheres, seasons are referred using their boreal definition: Winter is the average of December, January and February (DJF), and so on.

Observational Datasets

Three independent analyses of the observed SAT are used in this study: The CRU-TS4.02 monthly analysis from the Climate Research Unit of the University of East Anglia (Harris et al., 2014) is available on a 0.5° continental grid for the January 1901–December 2017 period, from http://www.cru.uea.ac.uk/cru/data/hrg/cru_ts_4.02/. Berkeley Earth's monthly analysis of surface temperature anomalies relative to the 1951–80 climatology (Rohde et al., 2013) is available on a 1.0° grid for the period January 1850–December 2015; it is downloadable from <http://berkeleyearth.org/data/>. Finally, the NASA Goddard Institute for Space Studies (GISS) analysis of SAT anomalies relative to the 1951–80 baseline (Hansen et al., 2010) is available on a 2.0° land-ocean grid for the January 1880–September 2015 period from <http://www.esrl.noaa.gov/psd/data/gridded/data.gistemp.html>. The data sets are converted to a common 0.5° resolution using bilinear spatial interpolation.

The Global Precipitation Climatology Centre (GPCC; Becker et al., 2013) provides a monthly analysis of precipitation from quality-controlled rain gauge data; GPCC's Full Data Reanalysis Version 8 data is available on a 0.5° continental grid from January 1901–December 2016, from <http://www.esrl.noaa.gov/psd/data/gridded/data.gpcc.html#detail>. Sahel rainfall is defined as the area-averaged rainfall within 20°W–40°E and 10°N–20°N, following Held et al. (2006).

Several climate indices are used in the study: The Atlantic Multidecadal Oscillation (AMO; Enfield et al., 2001 Kavvada et al., 2013) index was computed as the linearly detrended seasonal SST anomaly over the North Atlantic (75°W–5°W, EQ–60°N), following Enfield et al. (2001); SST from the HadISSTv1.1 analysis (Rayner et al., 2003) was used. An additional marker of AMO variability was the principal component extracted from an extended empirical orthogonal function analysis of HadISSTv1.1 SST data (Guan and Nigam, 2009). The Pacific Decadal Oscillation (PDO) index was obtained from <http://jisao.washington.edu/data/pdo/> where it is defined as the leading principal component of monthly SST anomalies in the North Pacific basin (poleward of 20°N; Zhang et al., 1997).

Desert Expansion

Two methods are used to quantify desert expansion during the 1920–2016 period. In both methods, a precipitation threshold is chosen to define the desert boundary; two threshold values—100 mm/year (or 0.274 mm/day) and 150 mm/year (or 0.411 mm/day)—based on previous definitions of the annual-mean Sahara boundary (e.g., Tucker and Nicholson, 1999 Berman and Dewit, 1983) are used. Two thresholds were considered so that sensitivity of the desert-area trend to the desert definition can be assessed. Desert area is computed by taking an area sum after weighting each latitude-longitude grid-cell area by the cosine of its latitude; GrADS function “*asum*” was used. In the first method, referred to as the area-trend method, the desert area is computed each year in each of the four seasons and annually, with average rainfall less than 0.274 mm/day (0.411 mm/day) defining deserts. The 1920–2016 linear trend in the computed area characterizes desert expansion/contraction over the 20th century.

In the second method, referred to as the endpoint method, the precipitation climatology (P_{clim}) and the linear trend in precipitation (P_{trend}) over the 97-year record are first computed at each grid point, seasonally and annually. These are used to create two maps: Precipitation at the end (from the plus sign in the following expression) and at the beginning (from the minus sign) of the record,

$$P = P_{\text{clim}} \pm (P_{\text{trend}}) * 47 \text{ years}.$$

The desert extent is then mapped in these synthetic 1920 and 2016 precipitation distributions at the endpoints of the record based on the chosen threshold, with the difference yielding desert expansion over the time period.

In both methods, the desert area computation is restricted to North Africa (northward of 5°N) to preclude inclusion of the Namib/Kalahari Desert, and to the west of 43°E to avoid inclusion of the Horn of Africa.

Each method has its advantages: The area-trend method is conceptually simple but it does not reveal the desert advance/retreat regions. The endpoint method is slightly more complex but it easily outlines the desert advance/retreat regions. Both methods should yield similar results except, perhaps, when the analysis period is comparable to the embedded variability timescales—a condition met with AMO, especially when it is influential on regional hydroclimate. The aliasing of multidecadal variability into linear trends would be inevitable in this case but with the two methods having different exposure to aliasing from the inverted order of the area-computation and linear-trend operations.

To remove the influence of multidecadal variability in the precipitation record, seasonally stratified precipitation fields are regressed onto the seasonal AMO and Pacific Decadal Variability—North Pacific (PDV-NP) SST principal components (PCs, which are orthonormal) over the full period (1920–2016). The influence of these multidecadal variability modes is computed by multiplying their time-independent regression coefficients by their time-varying PC, seasonally. The influence is then subtracted from the precipitation record, and the desert expanse recomputed, as above.

Statistical Significance

Statistical significance of individual linear trends at the 95% confidence level was assessed using the “AdjSE+AdjDF” approach of [Santer et al. \(2000\)](#). This method employs an effective sample size based on the lag-1 autocorrelation coefficient of the regression residuals.

Seasonal Climatology

The seasonal cycle of rainfall over the African continent is shown in [Fig. 1](#). Rainfall is larger, not surprisingly, in the summer hemisphere: Over tropical West Africa, Sahel, and Ethiopia in boreal summer (JJA), and over the Congo and Zambezi basins in austral summer (DJF). The similarity of the March–May and September–November rainfall distributions—with equatorial Africa, especially Congo basin being the rainfall focus—reflects the similar insolation distribution over the continent at these times—from the Sun being overhead twice at the equator each year, during the vernal (late March) and autumnal (late September) equinox. The Sahara Desert is, however, drier in spring than it is in fall, and the Namib/Kalahari Desert likewise in its spring than fall. The strong latitudinal gradient in precipitation at the southern boundary of the Sahara is a notable feature in all seasons, with the movement of this gradient over time having implications for regional agricultural productivity.

The desert boundary, based on the seasonally averaged rainfall threshold of 0.274 mm/day (or 25 mm/season), is shown in thick black contours in [Fig. 1](#). The Sahara expanse is largest in boreal winter and smallest in boreal fall (see [Table 1](#)); the larger threshold (0.411 mm/day or 37.5 mm/season) yields the smallest expanse in summer; both analysis methods return the same seasons for maximum and minimum expanse (cf. [Table 1](#)). In winter, the dry region extends from ~10°N to ~30°N but in summer, the Sahel rainfall pushes Sahara’s southern edge closer to 20°N. Likewise, the Namib/Kalahari Desert in Southern Hemisphere Africa is most expansive in austral winter, consistent with the notion of the desert location under the descending branch of the meridionally overturning Hadley Circulation; the Hadley descent is most intense in each hemisphere’s winter (e.g., [Nigam and Chan, 2009](#)).

The seasonal distribution of climatological SAT is also shown in [Fig. 1](#), using red contours. The warmest temperatures are found in boreal summer when SAT exceeds 33 °C over western Saharan Africa. The coldest temperatures occur northward of the Atlas Mountains in Algeria and Morocco in boreal winter. A local minimum in SAT exists over Ethiopia in all four seasons due to the high elevation of the Ethiopian Highlands. The spring and fall distributions exhibit less similarity in SAT than in rainfall, especially over Sub-Saharan Africa where SAT is notably higher in boreal spring; likely, because of the preceding dry season (winter) and depleted soil moisture stores which would preclude latent disposition of increased spring insolation.

Centennial Trends in Surface Air Temperature and Precipitation

The 1920–2014 period linear trend, obtained by averaging the linear trend in three independent analyses of SAT observations, is shown in [Fig. 2](#). Notable features include:

- Larger trends over Northern Hemisphere Africa, in all seasons.

Fig. 1 Seasonally averaged precipitation (brown-green shading; mm/day) and surface air temperature (SAT; red contours; °C) for the period 1920–2016. Precipitation is from GPCP and SAT from the CRU-TS4.02 dataset. The non-uniform shading interval for precipitation is indicated through the color bar. Contour interval for SAT is 3.0 °C. Fields are shown after 9 applications of the 9-point smoother (*smth9*) in GrADS. Thick red contours indicate the 30 °C isotherm, while thick black ones mark the 0.274 mm/day precipitation isoline. Note, 0.274 mm/day is equivalent to 100 mm/year, a precipitation-based definition of the annual-mean Sahara Desert boundary (Tucker and Nicholson, 1999). Major rivers are shown in thin blue lines and labeled in the top-left panel.

- A regional maximum over Sudan, particularly, in spring when SAT trends are larger than 1.5 °C/century; interestingly, this is the Nile River basin.
- A pronounced seasonality in trends over North Africa, near Algeria and Tunisia. Trends here range from ~0.8 °C/century in winter to as much as 2.0 °C/century in summer.
- A comparatively muted seasonality in trends over Southern Hemisphere Africa except for Angola, Namibia, and Botswana where austral winter (JJA) warming is stronger than in other seasons.
- The similarity in boreal winter and fall SAT trends over much of the continent.

Table 1 Expansion of the Sahara Desert: seasonally and annually during 1920–2016, based on the movement of the 100 and 150 mm year^{−1} precipitation isolines.

	Threshold (mm/year)	Winter (DJF)	Spring (MAM)	Summer (JJA)	Fall (SON)	Annual mean
Climatological Sahara extent (km ²)	100	14,057,000 (13,084,000)	10,743,000 (10,093,000)	7,858,000 (6,528,000)	7,809,000 (6,577,000)	7,518,000 (6,920,000)
	150	14,855,000 (13,998,000)	11,556,000 (10,829,000)	8,628,000 (7,622,000)	8,910,000 (8,137,000)	8,591,000 (7,967,000)
Sahara Expansion (km ²)	100	602,000 (578,000)	461,000 (410,000)	241,000 (140,000)	150,000 (35,000)	212,000 (302,000)
	150	532,000 (576,000)	426,000 (355,000)	262,000 (202,000)	114,000 (240,000)	346,000 (391,000)
Sahara Expansion (% of seasonal (annual-mean) climatological area)	100	4.3%; 7.1% (4.4%; 8.4%)	4.3%; 6.1% (4.1%; 5.9%)	3.1%; 3.2% (2.1%; 2.0%)	1.9%; 2.0% (0.5%; 0.5%)	2.8% (4.4%)
	150	3.6%; 6.2% (4.1%; 7.2%)	3.7%; 5.0% (3.3%; 4.5%)	3.0%; 3.0% (2.7%; 2.6%)	1.3%; 1.3% (2.9%; 3.0%)	4.0% (4.9%)
Countries Affected (obtainable only from the endpoint method; the ones in bold are most impacted by the desert advance)		Libya, Egypt, Western Sahara, Central African Rep., Cameroon, Nigeria, Guinea, Cote D'Ivoire, Sierra Leone, Ghana, Togo, Benin	Sudan, Chad, Niger, Nigeria, Mali, Senegal	Mauritania, Western Sahara, Sudan	Western Sahara, Mauritania, Sudan	Egypt, Mauritania, Mali, Chad, Sudan

The expansion is computed using both area-trend and endpoint methods; endpoint values are in parentheses. The areal values are rounded off to the nearest 1000 km² (which is about 1/3 of the 0.5° grid cell area at the equator). DJF refers to boreal winter months (December, January, and February), and so on. The impacted countries are identifiable only from the endpoint method; the ones in boldface are the most impacted by desert advance.

The seasonality of SAT trends can potentially modulate the amplitude of the seasonal cycle of SAT in the recent period. An increasing amplitude can worsen heat stress, as over central-southern Sudan (to the west of the White Nile) where 20th century SAT trends are large, especially in spring when the SAT peaks climatologically as well (cf. Fig. 1)—leading to hotter springs and increased heat stress. Likewise, over Northern Africa, including Algeria, Tunisia, and Libya, SAT trends are largest in summer, the season of greatest climatological SAT. In both these regions, the SAT trends amplify the seasonal cycle of regional SAT, intensifying heat extremes.

The linear trend in seasonal precipitation over the 20th century (1920–2016) is shown in Fig. 3 against the backdrop of the climatological dry regions (brown hatched). The centennial trends show interesting variations, corroborating the importance of seasonal analysis. For example, over Kenya and Tanzania, declining rainfall trends are present in boreal spring while increasing ones are present in fall and winter, each with socioeconomic implications. An annual-mean perspective, where offsetting seasonal trends average out, is not particularly relevant in understanding the impact of climate change on a continent where the seasonal rhythm of rainfall is the pace maker.

The rainfall decline is notably intense—with no seasonal offsets—over tropical West Africa. The decline is broadly focused on the source region of the Niger river, extending across several Gulf of Guinea rim countries (Senegal, Gambia, Guinea-Bissau, Guinea, Sierra Leone, Liberia, and Cote d'Ivoire). The rainfall decline exceeds 1.0 mm/day/century here, i.e., a 10–25% decline in seasonal rainfall over the course of the 20th century. The boreal spring decline is most impressive, percent-wise, and must lead to an increasing delay in the build-up of Niger streamflow after the dry winter season.

Another region showing rainfall decline in all seasons is the Congo river basin, especially the part encompassing Angola and the Democratic Republic of the Congo. Rainfall decline here is impressive in the shoulder seasons (spring and fall), with trends exceeding 0.6 mm/day/century where seasonal rainfall is ~6.0 mm/day. The thick brown lines in Fig. 3 mark the climatological desert boundaries, facilitating a visual assessment of desert expansion/contraction over the 20th century—the focus of the next section.

The African Great Lakes, especially Victoria and Tanganyika, are one of the few regions on the continent exhibiting increasing 20th-century rainfall, mostly in austral spring and summer. This is interesting because of the proximity of this region to the source of the Nile river, and implications for streamflow in the downriver region.

Change in Sahara Desert Expanse Over 20th Century

The overlay of 20th-century precipitation trends on the climatological dry zones in Fig. 3 suggests that the Sahara Desert has expanded equatorward. The Sahara's extent has been investigated using vegetation-zone boundaries as markers of desert expanse and its interannual variation (Tucker et al., 1991 Tucker and Nicholson, 1999). Although interesting because of the implicit seasonal context, these studies analyzed short records such as the recent 10–17-year long satellite-era ones. Unfortunately, desert trends over such periods reveal little about the secular changes in Sahara because of the potential aliasing of decadal-multidecadal variability into short-period trends.

Fig. 2 Linear trends in near-surface air temperature (SAT) over the African continent during 1920–2014. Average of the trends in three independent SAT analyses—CRU TS4.02, Berkeley Earth, and NASA-GISS—is shown after each was interpolated to 0.5° resolution. Contour and shading are at $0.4^\circ\text{C}/\text{century}$ interval. Fields are shown after 9 applications of the 9-point smoother (*smth9*) in GRADS. Country boundaries are shown in thin gray and major rivers in thin blue lines.

Here, we use the precipitation rate to demarcate the desert region. The use of precipitation rather than vegetation allows analysis of a longer record notwithstanding the spatiotemporal sparseness of the precipitation record in the early 20th century. A direct relationship between precipitation and the vegetation index found in previous studies (Tucker and Nicholson, 1999; Tucker et al., 1991) supports such a strategy. In Fig. 3, a 100 mm/year (or 0.274 mm/day; one of the two thresholds discussed in “Desert Expansion” section) precipitation isohaline demarcates the deserts, seasonally. A light brown hatching of the regions where climatological precipitation is less than this value marks the desert expanse which is monitored using the two methods discussed in “Datasets and Analysis Method” section.

Fig. 3 Linear trends in seasonal precipitation over the African continent during 1920–2016, from the 0.5° resolution GPCP dataset v8, in units of mm/day/century. The non-uniform *contouring and shading* interval is indicated via the color bar. *Thick solid brown contours* mark the 0.274 mm/day climatological precipitation isoline, and brown hatching indicates regions where climatological precipitation is below 0.274 mm/day (or 100 mm/year)—a precipitation threshold used for defining the Sahara Desert. Fields are shown after 9 applications of the 9-point smoother (*smth9*) in GRADS. Trends significant at the 95% confidence level are denoted with *black dots*. Major rivers are shown in *thin blue lines* and country boundaries in *thin gray lines*.

Sahara's Advance

The 20th century change in Sahara Desert's seasonal (annual) extent is displayed in Fig. 4B; the change is estimated using the endpoint method. Brown shading, which represents the desert's advance over the century, shows modest northward creep in boreal winter albeit not uniformly across longitudes; northward expansion is seen in Egypt and Libya, while modest desert retreat is seen in Algeria. The desert has encroached equatorward as well in winter, with notable intrusions in Nigeria, Cameroon, and the Central African Republic.

Fig. 4 (A) Advance/retreat of the Sahara Desert over the 1920–2016 period, *seasonally*. The *dashed (solid) brown lines* denote the 0.274 mm/day precipitation isolines in the synthetic 1920 (2016) precipitation map obtained from the endpoint analysis (cf. Section “**Datasets and Analysis Method**”). The *brown (green) shaded areas* denote desert advance (retreat). [Note, the observed precipitation distribution at the period endpoints cannot be directly used as it includes both interannual and decadal-multidecadal variability components and the sought-after linear trend.]. (B) Advance/retreat of the Sahara Desert over the 1920–2016 period, *annually*. Desert identification here is fully consistent with the canonical desert definition based on annual rainfall; a 100 mm/year threshold is used. Rest as in (A).

The centennial change in Sahara’s summer extent is primarily through the equatorward advance of its southern boundary (Fig. 4) which is climatologically located at $\sim 20^{\circ}\text{N}$ because of robust summer rainfall in the northern Tropics including the Sahel (EQ– 20°N ; cf. Fig. 1). Much as with the winter desert advance at the northern boundary, the southern advance is sectorally focused, with intrusions in Mauritania to the west and Sudan in the western sector, and desert retreat again seen in Algeria. The countries most impacted by the Sahara Desert’s seasonal and annual-mean advance are listed in Table 1.

The annual-mean desert advance (using the 100 mm/year threshold), displayed in Fig. 4B, provides context for the seasonal analysis and comports with canonical definitions of the desert based on annual-mean rainfall threshold (e.g., Tucker and Nicholson, 1999). The annual-mean advance shows primarily southward creep relative to the annual-mean desert boundaries.

Sahara's Expanse

A quantitative analysis of the centennial change in Sahara Desert's seasonal and annual-mean expanse is reported in Table 1. The primary analysis is based on the area-trend method but the endpoint method which generated Fig. 4 is also used with both desert definitions to assess the sensitivity of the desert expansion to analysis methods. The expansion has been largest (area-wise) in boreal winter (602,000 km², a 4.3% increase) and smallest in fall (150,000 km², a 1.9% increase) using the area-trend method with a 100 mm/year threshold. Estimates of desert expansion from the endpoint method (noted in parentheses in Table 1), with the same threshold, also yield maximum desert expansion in winter (578,000 km², a 4.4% increase) and a minimum in fall (35,000 km², a 0.5% increase).

The sensitivity of the desert expansion rate to the desert-defining precipitation-threshold is also reported in Table 1. A less stringent definition, based on a 150 mm/year threshold, leads to more expansive deserts—not surprisingly—but also smaller centennial expansions, indicating a tightening of the meridional precipitation gradient over the century. Percentages drop on both counts but Sahara's expansion remains robust with the largest expansion, as before, in boreal winter (532,000 km², a 3.6% increase). The weakest expansion again is in fall (114,000 km², a 1.3% increase). Results from the endpoint method using the larger threshold are qualitatively similar to those obtained with the lower one.

The sensitivity analysis indicates that while desert expansion and related area-percentage vary somewhat with the desert definition and analysis method, one can reasonably conclude that the Sahara Desert has grown larger, area-wise, more in winter than summer and fall. The countries bearing the brunt of the Sahara's southward advance in winter are the Gulf of Guinea rim countries, including Nigeria, Cameroon, and Central African Republic, and Mauritania and Sudan in summer (cf. Fig. 4B). Notable against these areas of desert advance (brown shading) over the northern continent are areas of green over Algeria in winter and summer, reflecting Sahara's retreat.

The expansion of the Sahara Desert is also analyzed using the conventional annual-rainfall based desert definition. Table 1 (last column) notes the findings from the area-trend and endpoint methods for both the 100 and 150 mm/year annual-rainfall thresholds. During 1920–2013, the Sahara expanded by over 212,000 km² (or ~2200 km²/year) based on the 100 mm/year definition, indicating a ~3% expansion over its climatological area (7,518,000 km²). The desert's southward creep is the major contributor to the expansion.

Sahara's Expanse: Variation and Potential Mechanisms

The Sahara Desert's expanse during the 1920–2016 period, and not just at its endpoints, is the focus of this section. The desert expanse in summer is plotted in Fig. 5, along with select indices of circulation and SST variability that can provide insights on causal mechanisms. The focus is on the summer season, when variations in the Sahara Desert's expanse arise mainly from the north-south movements of its southern boundary which borders the Sahel.

The summer expanse (solid black line) exhibits both an upward trend, highlighted by the linear fit (thin black straight line), as well as notable decadal-multidecadal variations. As areal changes result from the equatorward advance or poleward retreat of the desert's southern edge, Sahara's summer expanse should be inversely linked to Sahel rainfall (defined in "Observational Datasets" section) which is plotted with a dashed black line. The inverse relationship can be visually discerned: for example, the drying of the Sahel—a multidecadal decline in Sahel rainfall from the mid-1950s to the mid-1980s—is coincident with Sahara's expansion; the full-period correlation ($r = -0.78$) points to a strong inverse relationship. The anti-correlation allows tapping into extensive analyses of Sahel rainfall variability in the attribution of the summer waxing and waning of the Sahara Desert.

The Sahel rainfall has been linked to AMO variability among other processes, as noted in the introduction. To assess links between AMO and the Sahara's extent, two markers of AMO variability are plotted in Fig. 5 along with their correlations to Sahara's expanse and Sahel rainfall. The AMO SST principal component (dashed red line), obtained from an evolution-centric spatiotemporal analysis of seasonal SST anomalies in the 20th century (Guan and Nigam, 2009), shows higher correlations with both Sahara's expanse ($r = -0.49$) and Sahel rainfall ($r = 0.55$) in boreal summer.

Decadal SST variability in the Pacific basin, as typified by Pacific Decadal Oscillation (PDO; Mantua et al., 1997), is also linked with Sahel rainfall (Villamayor and Mohino, 2015; Nigam and Ruiz-Barradas, 2016) albeit not as strongly as the AMO. The PDO index, shown in Fig. 5 (solid blue line), is correlated with Sahel rainfall and Sahara's expanse at -0.34 and 0.27 , respectively. A contemporaneous statistical link between the PDO and Sahel rainfall seems more intriguing than the rainfall's link with the AMO because the AMO SST anomalies are proximal, with their tropical footprints offering potential mechanisms for their influence. In contrast, the PDO SST anomalies are distant and focused in the midlatitudes, disadvantaging them from the influence potential perspective, especially as only the tropical SST anomalies are generally viewed as influential on faraway regions. Interestingly, these disadvantages disappear once one recognizes that PDO is not without tropical links: Guan and Nigam (2008) showed the PDO counterpart in their spatiotemporal analysis (called Pacific Decadal Variability–North Pacific, or PDV-NP) to be linked with the

Fig. 5 Sahara Desert's expanse during 1920–2016. The boreal summer expanse is shown in the top using the *thick solid black line*. The *thin black straight line* is the linear fit to the desert expanse over the entire period—it is the basis of the area-trend analysis reported in [Table 1](#). Indices of sea surface temperature (SST) and rainfall variability with potential links to Sahara Desert's summer expanse are shown in the bottom panel, along with their correlation coefficients. For each index, r_1 (r_2) is the correlation between the index and Sahara expanse (Sahel rainfall). The Atlantic Multidecadal Oscillation (AMO) and Pacific Decadal Oscillation (PDO) are displayed using their common SST indices; an SST principal component (PC) based AMO index is also shown. The rainfall over Sahel is plotted as well. All time-series depict normalized anomalies after 10% Loess smoothing; the time-series for the latitude of the Northern Hemisphere (NH) subtropical jet was smoothed with a 20% Loess function. All time-series are normalized by their standard deviations; these are 703,903 km², 0.458 mm/day, 0.245, 1.005, and 0.977 for Sahara's summer expanse, Sahel's summer rainfall, AMO index, AMO PC, PDO index, respectively.

tropical Indian and Pacific basin SSTs. The PDO's modest influence on Sahel rainfall, if realized through its tropical Indian Ocean footprints, would be consistent with the findings of [Hagos and Cook \(2008\)](#).

Secular change is often characterized using the century-long linear trends in observational records, as for Sahara's expanse in [Fig. 5](#). The linear trend is however susceptible to the aliasing of multidecadal variability should the latter be prominently manifest in the record—the case in summer (cf. [Fig. 5](#)). The origin of the 95-year linear trend (referred as secular trend) in Sahara's summer expanse remains to be elucidated; the elucidation is challenging, especially, for an observational analysis. Trends on centennial and longer timescales can potentially result from the interaction of multidecadal variabilities (e.g., PDO and AMO) and, of course, from the increasing concentration of greenhouse gases and aerosol loading (e.g., [Held et al., 2006](#)) and the related secular change in SST distribution ([Nigam and Ruiz-Barradas, 2016](#); see their Fig. 23.6).

Concluding Remarks

The footprints of climate change over the African Continent are widely noted (e.g., [Niang et al., 2014](#)) but even region-specific descriptions seldom stray from the annual-mean displays of hydroclimate trends—and this over the African continent, where the seasonal waxing and waning of the Sahara Desert and the complementary expansion and retraction of Sahel rainfall rule the northern continent. Southern Hemisphere Africa is also no stranger to the munificence of the seasonal cycle which brings rainfall and life to vast stretches of the Namib/Kalahari Desert in austral summer. The utility of the seasonal perspective in climate change, i.e., seasonally-stratified centennial trends in precipitation and near-surface air temperature, for long-term water resource management cannot, of course, be overstated.

The centennial SAT trends are larger over the northern continent, especially in the northwestern sector and North Africa (Algeria and Libya) where they are often greater than 1.6 °C/century. The trends are furthermore pronounced in boreal summer, amplifying the regional seasonal cycle, i.e., making hot summers even hotter and exacerbating heat-related distress. Another focal point of large

SAT trends over north Africa is the region to the west of the White Nile (central-southern Sudan). For context, these SAT trends are not much smaller than the largest SAT trends over North America (e.g., Nigam et al., 2017, Fig. 1), that are manifest over western-central Canada in winter.

Centennial precipitation trends, especially the drying ones are notable over the tropical continent, i.e., in the region between the Sahara and the Namib/Kalahari deserts. River-basin wise, impressive drying trends are found in the source region of the Niger River from spring to fall, i.e., in the local rainy seasons; the decline is impressive because it represents a 10–25% decline in seasonal rainfall over the course of the 20th century. Another focal point of declining rainfall is the Congo River basin, and the Blue Nile source region around Lake Tana in Ethiopia; the latter in boreal summer—the peak rainfall season.

When viewed together, the key features of the centennial drying trends can be interpreted as the southward expansion of the Sahara Desert during boreal spring-to-fall, or alternatively, as the equatorward retreat of the northern edge of the Sahel rainfall belt. We show that the Sahara Desert has expanded over 1920–2016—by 2–4% depending on the season—using conservative estimates from the area-trend method. The southward expansion in summer is linked to the SST variability in the Atlantic and Pacific basins on multidecadal timescales, through Atlantic Multidecadal Oscillation (AMO) and Pacific Decadal Oscillation's (PDO) impact on Sahel rainfall. On centennial timescales, the summer expansion is related to aliased multidecadal variabilities and the increasing concentration of greenhouse gases and aerosol loading (e.g., Held et al., 2006).

The seasonally stratified analysis of hydroclimate trends—the focus of the study—was complemented by analyses of the annual-mean trends. The latter, more directly relatable to deserts in view of the canonical annual-rainfall based desert definition, also revealed expansion for the Sahara Desert over the 20th century (Table 1, Fig. 6). The rate is however sensitive to the analysis period, from exposure to the aliasing of multidecadal variability (e.g., AMO and PDO) and variability of the rain gauge network.

The aliasing of multidecadal variability in the linear trend in Sahara's annual-mean expanse is directly investigated during the relatively stable rain-gauge network period (1920-onwards) in Fig. 6. The AMO and PDO influences are removed from the precipitation record via linear regression. The annual-mean Sahara Desert expanse sans the multidecadal modes' influence is shown in Fig. 6 by the red curve. The AMO and PDO's influence is strong during the 1970s–90s when the red curve diverges from the black one; its contribution to the drying of the Sahel during the 1950s–80s is quite evident. The different linear trends of the two time series indicate that slightly more than half of the 2.8% increase in Sahara Desert's annual-mean expanse during 1920–2016 is attributable to multidecadal variability, and the remaining half to the rising greenhouse gas concentrations and aerosol loadings, and other factors.

Fig. 6 Annual-mean Sahara Desert expanse (km^2 ; computed from the area-trend method). The linear trend is shown for 1920–2016 (thin black line); the value is noted in the legend. The red curve and the corresponding 1920–2016 linear trend (thin red line) track desert expanse after removal of the Atlantic Multidecadal Oscillation (AMO) and Pacific Decadal Oscillation's (PDO) influence from the precipitation data set. The area-expansion percentages are all computed using the 1920–2016 climatological desert expanse.

The Sahara Desert has expanded by 2–4% over 1920–2016. The southward desert creep is pronounced at both ends of the tropical continent—in Mauritania and Mali in western Africa and in Sudan at the eastern edge of the continent. A more reliable measure of the land-area lost to desert encroachment each year is, perhaps, obtained by distributing the annual lost area uniformly across longitudes, which leads to a southward desert creep of about 2/3 Km each year along the entire ~5000 Km width of the Sahara. Future desertification will depend upon the phases of related sea surface temperature variability as well as anthropogenic effects. Continued expansion of the Sahara Desert will likely have significant implications for agriculture, water resources, and food security in the proximal countries.

Abstract

Weeds are the first stage of recovery following disturbances that reduce perennial plants and biological soil crusts (BSCs). This normal weed function can change when people transport weeds to habitats outside their home range. Freed from their usual consumers and competitors, some of the transported weeds invade the new habitats and replace local plants. Diversity, productivity, and stability decline. As their abundance increases, the invaders' dried remains often provide fine fuel that increases ignition and spread of lightning and human caused fires. In some regions, desert fire frequency has increased beyond the recovery ability of native vegetation and BSCs. This creates new plant communities dominated by weeds sometimes with a few of the smaller, faster-growing members of the original plant community. Control of invasive weeds requires public participation, inventories, habitat protection, monitoring systems, prioritization of species and sites, and strong financial support.

Weeds Characteristics

Plants that disperse rapidly, mature quickly, and tolerated drought and full sunlight, can colonize disturbed sites and grow free of interference by plants from the predisturbance vegetation.

While some plants live long deliberate lives of hundreds or thousands of years, natural disturbances opened an alternate evolutionary pathway for weeds. Except for the spreading roots of a few species and some short-lived trees, most weeds live only 1 or 2 years. Even among those with long-lived roots, the parts we see, the shoots are short-lived.

Weeds' short lives and their preference for full sun does not allow them to compete with large, mat-forming, shade-casting, long-lived climax species of the desert grasslands, shrublands, woodlands, and forests. During the normal course of events, those species spread back into disturbed sites and replace the weeds. The long-lived plants persist until another catastrophe exposes the soil and allows the weeds to return.

In deserts, drought-tolerant weeds spread across upland slopes, and moisture-dependent invaders spread on the banks of streams and springs. Rabbitfootgrass (*Polypogon monspeliensis*) in Fig. 1, is a weed of moist habitats that invades along the banks of desert streams. However, weeds are the supreme opportunists, capable of rapid spread during brief benign periods. And many can reproduce at a broad range of sizes. When moisture is limited, summer cypress (*Kochia scoparia*) for example, can mature and produce a single spike of seeds at a height of three centimeters. When sufficient moisture is available, summer cypress can reach four meters in height and produce many seed laden spikes. Weeds that colonize stream banks can spread to upland habitats following periods of above average rainfall. They may seem to disappear when average conditions return, but many leave behind persistent propagules ready to continue advancing in future wet periods.

Fig. 1 Rabbitfootgrass (*Polypogon monspeliensis*). This moisture-loving grass probably originated in Europe, but it became a global cosmopolitan so early in human history its origin is uncertain. This one is growing beside the Agua Fria River, a small desert stream in central Arizona, United States. Rabbitfootgrass can spread through dry upland sites by following roadside ditches where it joins a diverse collection of invasive weeds.

Few weeds of the deserts grow well in the shade of other plants. In most instances, weed establishment requires disturbed habitats. Some invasive weeds might be capable of invading undisturbed natural vegetation, but determining this is difficult. Livestock grazing, food and fuel gathering, and farming have damaged ecosystems across the desert biome.

In their rapid response to vegetation destruction by construction, fires, floods, and foraging animals, weeds resemble human first responders. Weeds cover exposed soil and provide protection from erosion. Following geomorphic events such as landslides, weed roots and decaying parts bind sand and gravel and rebuild the soil.

However, when people disperse weeds beyond their normal range, problems can develop. Freed from home range predators and competitors, a few introduced weeds will invade local habitats and replace climax plants.

Dispersal

Animals, wind, water, and people walking, boating and driving serve as weed dispersal vectors. [Frenkel \(1970\)](#) once analyzed the debris traps of the drains at a car wash and found the propagules of over 400 species. Most weed propagules spread adhered to surfaces, moving through guts, or mixed with seeds of agricultural crops. However, people have planted many weeds to provide soil stabilization, produce food for livestock and people, serve as garden ornamentals, and more. On numerous occasions, introduced species have spread beyond their intended purpose, invading native vegetation with disastrous effects. For example, many nurseries sell Dalmatian toadflax (*Linaria dalmatica*) for flower gardens. Toadflax ([Fig. 2](#)) roots delve deep, persist for years, and may send up shoots outside flowerbeds. Controlling Toadflax is easy in small gardens and yards, but seeds often spread into native vegetation. Once established, the plant's deep root system has allowed it to become a permanent resident across thousands of hectares of arid shrub and woodlands.

Weed dispersal vectors deposit propagules along roads and fences, beneath the distal tips of tree and shrub branches, and on the margins of irrigated pastures and crops. Besides seeds, weed propagules include underground rhizomes, surface stolons, and vines. These organs can grow 10 m or more per year, but none of them attains the velocity achieved by the seeds of weeds whose seedpods explode when they become dry. These botanical cannons propel their seeds surprising distances. The bursting seedpods of creeping woodsorrel (*Oxalis corniculata*), a petite weed of stream banks and field margins, can shoot seeds over three meters.

Most introduced plants do not spread or even survive to form a persistent population. Some grow scattered among other plants and have limited impact. Some remain in small patches for years and then begin to spread. However, less than 10% of the hundreds of plant species people accidentally or intentionally introduce to the deserts will invade and replace native vegetation.

Fire

Fire was not important in deserts before invasive weeds arrived. Unlike plants of the temperate grasslands and semiarid evergreen woodlands and forests, desert plant cover is often too discontinuous for fires to spread. In fact, [Rogers and Steele \(1980\)](#) found almost no fire-tolerant traits among the dominant shrubs and trees of the Sonoran Desert. Introduced weeds that invaded the Great

Fig. 2 Dalmatian toadflax (*Linaria dalmatica*). This common horticultural flower, spreads by seeds and long-lived underground roots.

Basin Desert in the 19th century (Watson, 1871) provided a new source of fine fuel that facilitated ignition and spread of fires. These weeds became the most disruptive invasive species on Earth (Brooks et al., 2004). These weeds are more efficient than natives are at extracting moisture and nutrients from desert soils. They fill the gaps between perennial plants and give fires continuous fuel in which to spread. Over the past century, desert fires have decimated millions of hectares of desert vegetation. Figs. 3 and 4 illustrate the change from shrubland to grassland dominated by fire prone weeds (fireweeds) in the cool-climate Great Basin Desert. Fig. 5 illustrates the same change in the warm-climate Sonoran Desert.

Triangle bursage and brittlebush (*Ambrosia deltoidea* and *Encelia farinosa*) with an understory of the invasive annuals dominate rocky slopes. Before the 1974 fire tall saguaro and rounded paloverde and ironwood (*Olneya tesota*) in a matrix of shrubs covered and crowned the slopes and ridges.

Fig. 3 Cedar Mountains, United States, 1901. This photograph illustrates typical salt desert shrubland dominated by Shadscale (*Atriplex confertifolia*) at lower elevations of the Great Basin Desert. Photograph by G. K. Gilbert © U. S. Geological Survey Photograph Library (public domain).

Fig. 4 Cedar Mountains, United States 2008. Matching the scene in **Fig. 3**, this photograph taken September 1, 2008 shows that most of the shrubs are gone. The loss of plant cover is particularly striking on the slopes at the base of the cliffs. A dry thatch of cheatgrass (*Bromus tectorum*) and redstem filaree (*Erodium cicutarium*) covers the ground.

Fig. 5 Saguaro fire site, February 29, 2008. Two fires (1974 and 1987) transformed the saguaro-paloverde (*Carnegiea gigantea*-*Parkinsonia microphylla*) woodland of this Sonoran Desert site to an annual grassland dominated by the invasive annuals, red brome (*Bromus rubens*), redstem filaree (*Erodium cicutarium*), and more.

Biological Soil Crusts

Two groups of microorganisms are important constituents of desert ecosystems. Biological soil crusts (BSCs) composed of soil particles, cyanobacteria, algae, microfungi, lichens, and bryophytes form thin layers on exposed soil surfaces between desert plants. BSCs cover and stabilize the soil, capture nutrients, and retain moisture. They make up over 70% of the living ground cover in parts of the deserts. BSCs develop best with full sun exposure, and their cover increases as annual precipitation and vascular plant cover decrease. **Fig. 6** shows a common biological soil crust of the cool Great Basin Desert. Though the rough texture traps wind-blown seeds, few roots penetrate the crust's surface.

Fig. 6 Pinnated biological soil crust in a protected area of the Great Basin Desert. Such crusts allow desert soils to accumulate moisture and nutrients and they block invasive weeds. Livestock trampling can eliminate them.

Arbuscular mycorrhizal fungi (AMF) sheath and connect the roots of desert plants. AMF are obligate symbionts whose carbon nutrition depends on the photosynthetic success of their host plant. They benefit hosts by facilitating absorption of water, phosphorus and other micronutrients, and they can increase nodule formation by nitrogen-fixing bacteria.

Well-developed BSCs and AMF help prevent entry by invasive weeds. BSCs limit germination sites and AMF increase the success of native plants and can inhibit the growth of invasives (Vogelsang and Bever, 2009). Wheeled vehicles, livestock trampling, and fire can destroy BSC and AMF continuity. Like desert vascular plants (Rogers and Steele, 1980), BSCs, and AMF can take decades to recover (Root et al., 2017).

Invasive Weed Management

Early detection of new weeds is critical. In just a few years, invaders can form large colonies with many distant satellite populations. Rapid response measures must be ready to control or eradicate detected invaders before they can spread. Managers prepare treatment plans for invaders, establish schedules for repeated surveys, and enlist public help in finding and treating invaders. Detailed information for weed management is available online from the North American Invasive Species Management Association. The Center for Agriculture and Biosciences International (location) provides news and national weed control plans and policies indexed by subject and by location.

Strategic Concepts

Adaptive management

Numerous biological and environmental factors make weed growth so unpredictable that weed managers view all treatments except the most direct physical removal of weeds as experimental. They define the methods and study the results of each treatment to gain insights that allow shifting tactics to improve results.

Justification for invasive weed management

The field of Weed Science developed in response to the loss of crop yields because of weed invasions. Learning to measure the economic cost of wildland invasions has taken longer but is now well developed (Farber et al., 2006). De Groot et al. (2012) provide estimates of the monetary value of ecosystems and their services across global biomes, and Naylor (2000) discusses the reduction of ecosystem services by invasive species.

Prevention, regulation, and ecosystem maintenance

Weed management involves defense and target hardening. Defense requires policies and regulations to stop weed imports by people, livestock, and equipment. Target hardening requires landuse policies that maintain healthy native vegetation. Many regions have border inspection regulations in place to prevent entry of plants and diseases that invade farms and natural vegetation. Likewise, weed managers work with other landuse managers to promote public education and sustainable landuse. For example, the Play, Clean, Go program cited below in the List of Relevant Websites publicizes the invasive species problem and enlists citizen participation in curtailing weed spread.

Early detection, monitoring and response

Effective weed control requires rapid detection and response. The goal is to prevent maturation and seed production by potential invaders. It requires preliminary inventories and regular monitoring to discover new populations before they can spread. Because of the uncertain survival of new weeds, the first response to most species is establishing a monitoring schedule. This does not apply to weed species known to be invasive in similar sites.

Satellite populations

Weed populations grow by expanding their boundary and by long-distance dispersal to establish satellite populations. Since a single plant can produce thousands of seeds, tiny satellite populations of one or a few plants can serve as significant sources for further invasion. As the area of an infestation grows, the proportion of each plant's propagules falling among the plants within the occupied area will increase and the proportion falling outside the area will decline. Thus, the rate of expansion will decrease as the infested area grows. Because the rate of expansion is greater for small satellite populations, managers give treatment of satellite populations the highest priority.

Coordination with neighbors

Property boundaries do little to influence weed dispersal and establishment. Fences may stop the first wave of tumbleweeds, but they are not an effective barrier. Coordinating prevention, inventory, and control with neighboring agencies and private landowners is part of weed management planning.

Control versus eradication

Immediate eradication of invasive species is sometimes the most cost effective option. Annual costs to control weeds increases as new species arrive and existing species spread and establish satellite populations. Even though eradication of a widespread species is difficult and costly, it might be essential to preserve high-priority habitats. [Mack and Foster \(2009\)](#) found that eradication requires the following:

1. An effective prevention plan,
2. An exhaustive inventory,
3. Readily visible target species,
4. Accessible and easily inventoried and monitored terrain,
5. Target species with short-lived seed banks (3 years maximum),
6. Target species with small enough range that available resources are adequate for inventory, eradication, and monitoring,
7. Monitoring support well past the expected duration of the seed bank. Otherwise, seedlings and other individuals missed in inventories, treatments, and subsequent monitoring will produce new seed banks.
8. Guaranteed continuity of public and financial support.

Inventory

Inventories to discover and map invasive species rely on two approaches. The first is for areas of continuous weed cover. It produces vegetation maps made from sample observations and aerial photographs. The second method is for areas of scattered weed presence. It creates descriptions and small maps of weed occurrence. Continuous weed cover develops as repeated fires, floods, or overgrazing weaken and remove native vegetation. Scattered weed presence occurs around trees, along fences, and in patches of disturbed vegetation. Since some weed species become invasive after years of quiet residence, initial inventory maps and descriptions should include all known weed species. Managers can treat known invaders immediately and set monitoring schedules for other weeds.

Prioritizing Weed Species and Sites in Deserts

Prioritizing species

Prioritization equips weed managers for immediate response when known invaders appear. The practice begins with literature searches for information on the ecology, distribution, and control of each individual weed species. The information produced by the searches will provide a first approximation of the relevant characteristics and control treatments for species in, or likely to reach a management area. Critical considerations for prioritizing species include potential for arrival, establishment, spread, and

impact. Large invasive-species data sets are available from the Global Register of Introduced and Invasive Species and the Invasive Species Compendium hosted by the Center for Agriculture and Biosciences International. Internet links for these and other Internet information sources follow the references.

The ideal prioritization system integrates ecological knowledge of individual species with site conditions, and adjusts with monitoring information and observed results of treatments.

Prioritizing sites

Hobbs and Humphries (1995) proposed ranking sites for weed control based on two factors, ecosystem value and level of site disturbance. Protected parks, wilderness areas, and critical habitats such as desert streams (Fig. 7) have more ecosystem value and should receive the greatest weed-control effort.

The diagram below (Fig. 8) illustrates possible weed management responses for sites and species of varying priority.

Numbers in cells (not including the left column) indicate the recommended frequency in years for monitoring existing infestations. The “0” in the cells for highest and high priority sites and weeds show rapid response instead of monitoring. The seasonal timing of observations follows maturation of the weeds. The term “withdraw” indicates intervention to limit human disturbances. Sites in the cells at lower right are monitored to detect appearances by high-priority species. Depending on resources and proximity to high-value sites, managers might eradicate such species.

Treatment

Treatment tactics vary for each weed species and each site. They include pulling and cutting, chemical herbicides, releases of predatory insects and microorganisms imported from homelands, planting native species, prescribed fires, and combinations of these. Published information on individual weed responses to some treatments is often available, but for many weeds, results of treatments are unpredictable.

Restoration

Healthy native vegetation resists weed invasions. However, eradicating invasive weeds and preventing their return while aiding establishment of native species is difficult and expensive. Weeds often leave behind persistent propagules, changed soil chemistry,

Fig. 7 Damaged streambank. Water diversions, livestock, human travel and settlement, and floods disturb desert riparian habitats. The site in this photograph retains high value despite the impacts because it is a perennial stream with a relatively large willow-cottonwood riparian forest occupying the floodplain.

Prioritization for Species and Sites with Management Actions

Medium (2)	(0) Withdraw, begin control treatment.	(2) Monitor, treat if expanding.	(3) Monitor.	(5) Monitor.
Low (3)	(1) Withdraw, begin control treatment.	(3) Monitor, treat if expanding.	(5) Monitor.	No Action.

Fig. 8 Priority sites and species. Numbers in the left column represent the minimum number of years between weed inventories. Highest-priority sites receive two or more visits each year because some species germinate throughout the growing season and others germinate during spring or during summer.

and depleted soil microorganism communities. Restoration costs are justified only for the highest priority sites. The Society for Ecological Restoration supplies information with examples and techniques on the organization's website.

Explaining Invasions

Eurasia has produced most of the invasive weeds found on other continents. The larger Eurasian deserts, with their broad connection to North Africa, their great environmental variability, and their long history of Old World human occupation and disturbance created pressures for Eurasian weeds to evolve better dispersal, establishment, growth, and reproduction abilities than the weeds of Africa, Australia, and the New World. For example, no North American weeds can match the overwhelming success of cheatgrass, redstem filaree, and others that have spread across the arid western US.

Weeds grow and spread in new habitats because they are free of their homeland predators and competitors. Casual and formal tests of this "escape hypothesis" have had mixed results, but most support the idea. For example, [Lucero \(2018\)](#) found granivorous rodents preferred seeds of native brome grass and left more seeds of the invaders to spread and germinate.

Predators, competitors, and environmental conditions restrain most introduced weeds. Those that spread after a period of stasis might do so because of environmental changes or because they have made genetic adaptations to the new conditions.

The most successful desert invaders are those that mature and dry by late spring or early summer and produce fire-tolerant seeds. As mentioned above, these fireweeds are spreading, and fueling destructive desert fires that are wiping out native shrubs and trees.

The Future

Disturbances of native vegetation and introductions of new weeds are increasing. As climate change intensifies, disturbances will multiply. The traits of invasive weeds that let them colonize new sites—their short lives, high mobility, rapid reproduction, and genetic adaptability—also equip them for success as weather and climate change. Without increased control efforts, a legacy of the Anthropocene will be weed dominance of the desert biome.

Abstract

Livestock production occurs in all deserts (except for polar deserts) worldwide. In many desert areas, it is the single most significant human impact. Livestock production includes the grazing of plants, but also all associated activities that occur to produce domestic animals. This consists of the dewatering rivers for irrigated forage crops, killing of predators and “pest” species, forage competition between native and domestic animals, soil compaction and erosion, changes in fire regimes, spread of alien plant species, loss of biodiversity and numerous other ecosystem effects.

Introduction

Worldwide some 3 billion hectares of land, including deserts, are grazed by domestic livestock and the majority suffer degradation and loss of biodiversity as a result (Carter et al., 2014).

Deserts are usually defined as arid or semi-arid landscapes often with high evapotranspiration rates, high rates of solar radiation and large daily and seasonal temperature range. These factors limit the plant and animal life that can survive in these environments, although there are many remarkable adaptations that species have developed to deal with these extreme conditions.

Many people associate the term desert with “hot” temperatures like the Saharan desert in Africa or the Sonoran Desert in Arizona and northern Mexico which are found where descending air creates dry zones. However, many other deserts are colder, often associated with the rain shadow effect of mountains. Cold deserts like those found in Central Asia (Gobi) or Great Basin in North America will often get snow cover for part of the year. The polar desert in Antarctica is the largest desert area in the world and is almost entirely snow-covered year-round.

No matter where they are found, all desert zones experience periods of acute shortages of precipitation and this has significant implications for the human ability to exploit the ecosystem with livestock grazing. Domestic livestock includes grazing animals such as cattle, sheep, goats, horses, donkeys, yaks, camels, and other species (Fig. 1).

Humans have traditionally used marginally productive landscapes and steeper terrain mountainous areas for livestock production, while better-watered landscapes and flatter terrain are reserved for crop production. Except for irrigated landscapes, most deserts have limited ability to support crop agriculture other than hay or pasture. Consequently, livestock grazing is often the dominant economic use.

With the exception, of the polar deserts, most of the world’s desert areas experience some amount of livestock grazing. Indeed, ungrazed reference points or refugia where livestock grazing has not occurred is difficult to find. (Note unless otherwise noted, when I use the term “grazing” I am referring to cropping by domestic livestock.)

Throughout the world’s deserts, there are many native herbivores. In North American deserts, native herbivores include insects like grasshopper (*Melanoplus* spp.), rodents like ground squirrels (*Spermophilus* spp.), pig-like javelina (*Tayassu tajacu*) to larger ungulates like mule deer (*Odocoileus hemionus*) or pronghorn antelope (*Antilocapra americana*). Herbivores like kangaroos (*Macropus*) are found in Australian deserts, while Asia and Africa have even more large native herbivores.

Though there are many native herbivores, it’s important to note that this does not necessarily mean those plant communities are adapted to exotic domestic livestock grazing. Exotic livestock do not utilize the landscape in the same way as native species. And

Fig. 1 Cattle and water tank in Mojave National Preserve, California.

even when a species might be “native” to a particular ecosystem, the tendency to maximize profits and animal production leads to excessive domestic animals that are above the ability of the landscape to support.

As a generalization, livestock grazing is one of the major human activities responsible for creating or expanding desert areas through the process of “desertification” (<https://www.env.go.jp/en/nature/desert/download/p2.pdf>, accessed 3-12-2019).

The vegetation in most deserts outside of the polar regions is characterized by grasses, shrubs, and scattered trees. Grasses and shrubs are the dominant forage utilized by domestic herbivores.

Aridity has its limitations on livestock production and tends to exaggerate the ecological impacts of livestock.

First, compared to other ecosystems, the lack of precipitation limits plant growth. Regarding primary productivity, desert ecosystems have some of the lowest primary productivity (rate at which energy is converted by photosynthetic and chemosynthetic autotrophs to organic substance) on earth. For instance, the United States (U.S.) General Accounting Office (GAO, 1991) concluded that “hot deserts are among the least productive grazing lands in the United States.” An appraisal conducted in 1984 by U.S. Bureau of Land Management (BLM) and the U.S. Forest Service found that more than 160 acres of land were sometimes required to support one cow for 1 month in southern New Mexico, Arizona, southwestern Utah, southeastern California, and most of Nevada (GAO, 1991).

One of the significant characteristics of desert landscapes is variable precipitation. Precipitation has a huge effect on plant growth. Drought conditions are more likely in desert regions and typically will last longer than in other ecosystems. Since much plant growth is dependent on the amount and timing of precipitation, prolonged drought can significantly reduce the annual plant biomass production and thus the forage to support livestock.

The cumulative impact of livestock is more than “grazing” or “browsing” (see below), rather these should include the collateral damage from livestock “production” (Wuerthner and Matteson, 2002). A 1994 U.S. Forest Service report concluded that livestock grazing was the 4th major cause of overall species endangerment and the 2nd major cause of plant endangerment (Belsky et al., 2002).

As the U.S. General Accounting Office (GAO, 1991) concluded in a report to Congress: “Current livestock grazing activity on BLM allotments in hot desert areas risks long-term environmental damage while not generating grazing fee revenues sufficient to provide for adequate management. GAO found evidence of damage occurring on BLM lands as well as evidence of livestock grazing’s adverse impacts on several wildlife species. Some damaged lands may take decades to recover if they recover at all.”

Among the well documented direct impacts of livestock production on desert ecosystems are the destruction of soil crust, damage to riparian areas, forage competition with native wildlife, the spread of invasive weeds, changes in plant community composition, and losses in carbon storage.

Other aspects of livestock production include disease transmission from livestock to native wildlife, water pollution, the killing of “pests” and predators to protect livestock, the dewatering of rivers for irrigation and the “capture” of springs and other water sources for livestock (Wuerthner and Matteson, 2002; Fleischer, 1994).

Not all species are negatively impacted by livestock production. For instance, brown-headed cowbirds (*Molothrus ater*), a nest parasite, increase with more domestic cattle. Sagebrush sparrow (*Artemisiospiza nevadensis*) likely “benefited” from the shift from grasslands to more shrublands in some cold desert ecosystems (Bock et al., 1993). However, in most cases, the species benefiting are wide-spread generalists, while those harmed by grazing tend to be rarer or those with special habitat needs.

As Bock et al. (1993) concluded in one research review “The problem with livestock across much of the West today is not with their presence, but with their ubiquity.” Those plants and animals, including neotropical migratory birds, intolerant of activities of domestic grazers have comparatively few places left to live.

Specific Livestock Impacts

Soil Crusts

One of the essential negative impacts from domestic livestock, particularly animals that are herded in tight groups, is the trampling of soil crusts. Soil crust is important components of arid to semi-arid ecosystems. Soil crusts are known by many names including biocrusts, cryptogamic, cryptobiotic, microbiotic, or microphytic crusts. Soil crust consists of cyan bacteria, fungi, lichens, mosses, and green algae and may consist up to 70% of the plant cover in some communities. Indeed, in many desert ecosystems, there are more species of soil crusts than vascular species (Fig. 2).

By covering the soil, biocrusts reduce wind and water erosion as well as act as a mulch helping to retain soil moisture. Many soil crusts can fix atmospheric nitrogen, so it's available to other plants. They also affect carbon storage, and influence plant germination and growth. Notably, nitrogen is one of the limiting factors in many desert areas. In some desert locations, nitrogen fixation by soil crust is often one of the most important sources of nitrogen (Evans and Belnap, 1999).

Crusts often play a critical role in soil productivity. Many biological soil crusts in western North America are dominated nitrogen-fixing cyanobacteria and lichens. Micro fungi also weave filaments through the top portions of the soil, holding the soil particles together.

While many desert vascular plants have adaptations to assist in germination such as self-burial mechanisms or rely on rodents for caching seeds, but unlike native species, many exotic species like cheatgrass (*Bromus tectorum*) lack such adaptations and can be inhibited from successful germination by intact soil crust.

Livestock grazing, by destroying soil crusts, also increases the occurrence of wildfire that is one of the major threats to sagebrush ecosystems, and wildlife like sage grouse (*Centrocercus minimus*).

Soil Compaction and Trampling

Trampling and compaction of soils is an unavoidable impact from domestic livestock. The destruction of soil crusts, reduction of water infiltration, as well as removal of vegetative cover has led to increased soil erosion. A lower infiltration rate means less water will be available for plants and more surface erosion may occur.

For instance, an experiment in Arizona looked at how vegetation changes have led to increases in interrill areas, decreases in runoff infiltration and possibility of greater susceptibility to frost action (Abrahams et al., 1995).

Soil compaction reduces water absorption for plants including making it more difficult for them to spread their roots (Boarman, 2002). A review of grazing impacts on hydrological impacts concluded that grazing at any intensity reduced water infiltration (Gifford and Hawkins, 1978).

Water run-off experiments tests showed that compared to lightly grazed areas, moderate grazing areas had seven times the runoff and heavily grazed areas had 10 times the runoff as lightly grazed areas (Boarman, 2002).

Another effect of soil compaction and erosion are changes in soil temperatures. In fact, grazing by livestock can increase soil temperatures; hence water evaporation as well as amplifying the already hot conditions found close to the ground in desert areas. For instance, a significant increase in soil temperature at depths of 2.5, 7.5, and 15 cm was observed in clipped versus unclipped plots (Steiger, 1930).

Trampling by hooves also can affect seeds biomass. A study in the Mojave Desert (U.S.) found native seeds were higher in an area protected from livestock grazing and off road vehicles (examples of vehicle types) compared to areas outside of the enclosure, even though there were more seed-eating rodents inside the enclosure as well (Brooks, 1995).

Fig. 2 Biocrust cover soil surface reducing erosion, and water losses.

Riparian Areas

Riparian areas are those lines of water influenced green vegetation found along waterways. Estimates suggest that riparian areas occupy about 1–2% of the land area in many arid landscapes. Despite their relative scarcity, their combination of water, and lush vegetation growth, these thin, green lines are very productive sites, and ecologically critical to 60–70% of wildlife in the western United States. Riparian areas support about a third of all plant species found in the arid West, and one study of Arizona arid lands concluded that 70% of all threatened and endangered species are riparian obligates (Johnson, 1989) (Fig. 3).

The highest densities of breeding birds in all of North America are reported from southwestern riparian woodlands. More than 75% (127 of 166) of southwestern bird species nest primarily in riparian woodlands and neotropical migrants comprise 60% of the 98 landbirds (Bock et al., 1993).

Due to the abundance of green vegetation, shade, and water, riparian areas are particularly attractive to domestic livestock. Their foraging in these areas has multiple impacts (Behnke and Raleigh, 1978; Kauffman and Krueger, 1984; Armour et al., 1991; Poff et al., 2012). These include trampling and break down of banks and channel entrenchment. Livestock alters the stream channel leading to more extensive and shallow profiles. These channel modifications in turn lead to higher stream temperatures and velocities which can be detrimental to fish including a three to four times decline in trout (*Salmo*) in grazed versus ungrazed stream sections (Fig. 4).

Another review study documented that livestock grazing was found to affect water quality and seasonal quantity negatively, stream channel morphology, hydrology, riparian zone soils, instream, and streambank vegetation, and aquatic and riparian wildlife (Belsky et al., 1999).

Fig. 3 Riparian areas are critical to 60–70% of wildlife. Here cattle have eliminated streamside vegetation, broken banks, and compacted soils.

Fig. 4 Cattle grazing riparian area on the Tonto National Forest, Arizona.

Browsing on streamside shrubs and trees like willow reduce shading of the creek as well as habitat for nesting songbirds. More than 75% (127 of 166) of southwestern bird species nest primarily in riparian woodlands and neotropical migrants comprise 60% of the 98 landbirds (Johnson et al., 1977).

Soil compaction from livestock (as discussed above) reduces water infiltration and the “sponge” effect of riparian areas. The loss of sponge effects can lead to a reduction in late season flows.

Removal of grass and other streamside vegetation by livestock reduces hiding cover for many species. For instance, sage grouse chicks rely on tall streamside vegetation for feeding as well as hiding cover (Thompson et al., 2006).

When grass is cropped to golf course height (1 cm), many species from amphibians to reptiles to birds and mammals in riparian areas are exposed to predators.

Forage Competition

As previously stated, productivity in arid climates is generally low; thus, any forage removal by domestic animals can have a disproportionate impact on native species (Willers, 2002). For instance, desert tortoise (*Gopherus agassizii*) remain in their burrows for extended periods and only emerge to feed when their favorite foods are green and nutritious. Tortoises selectively feed on herbaceous vegetation that is also the same plants favored by domestic livestock. In fact, Avery (1998) in the Mojave Desert demonstrated that tortoise foraging behavior was altered where cattle and tortoises overlapped. In the absence of livestock, tortoises primarily ate herbaceous perennials (91% of diet), whereas, in the grazed areas, tortoises mainly ate annual grasses (59%) followed by herbaceous perennials (21%). Enough forage removal by livestock affected tortoise reproduction with fewer eggs laid in drought years where livestock competed with tortoises for food (Tracy, 1996).

Another example can be found in sage grouse. Although the sage grouse as its name implies relies on sagebrush (*Artemisia* spp.) much of the year, the chicks rely on forbs during the first 4–6 weeks of their lives. Grazing by domestic livestock can remove many of these favored plants.

A third example can be found with desert bighorn sheep (*Ovis canadensis nelsoni*; Fig 5). Domestic sheep and bighorn sheep consume substantially the same foods, and if a herd of domestic sheep moves through wild sheep habitat, they can leave little forage for the bighorns.

Fig. 5 Desert Bighorn sheep

Social displacement also influences forage use. Many native species avoid areas that are actively being grazed by domestic animals. Studies have documented that mule deer, pronghorn, and elk (*Cervus canadensis*) will avoid grazing in the same pastures as domestic animals and are displaced—presumably to less suitable habitat. For instance, in one study in a mountain uplands (so not desert), 94% of the observations of elk *Cervus canadensis* occurred in pastures which were unoccupied by livestock (Frisina, 1992).

Another impact of “forage competition” is the loss of hiding cover for small mammals, reptiles, and ground-nesting birds. For instance, sage grouse are dependent on having tall vegetation to hide their nests from predators (DeLong et al., 1995).

Invasives and Weeds

Invasive plants and animals are species that are either exotics from other countries, or native to the region but found in a new location. Among the most problematic invasives in the western US deserts are cheatgrass (*Bromus tectorum*), and Russian thistle (*Salsola tragus*) that are favored by disturbance caused by livestock. Other exotics are purposely planted to improve forage for livestock like crested wheatgrass (*Agropyron cristatum*). As a result of these factors, the spread of exotics is facilitated indirectly or directly by livestock.

Water Competition

Water is typically scarce in desert ecosystems. There are three primary ways that livestock production impacts water: (1) direct water consumption and pollution; (2) dewatering of natural water sources like rivers and springs for irrigation to provide hay for supplemental forage; and (3) construction of dams and reservoirs primarily to store water for irrigation.

In many deserts, natural springs and seeps are tapped to provide water for domestic animals that can reduce the availability for native species. Not only do domestic animals often trample the areas around such water sources, often leading to soil compaction and a reduction of flows, but ranchers usually pipe flows into water troughs, making it more difficult for native species to access. Loss of springs and seeps via dewatering has been shown to reduce native snails (Frest Terrance, 2002) and amphibians (Engle, 2002).

The mere presence of domestic animals may socially displace native species. Some native species will wait until domestic animals are absent before they access waterholes. For instance, a study of pronghorn (found that nearly one-half of pronghorn—feral horse interactions resulted in the exclusion of pronghorn from the water).

The production of hay as supplemental forage for livestock is common in desert areas. Nearly every natural meadow along streams has been converted from natural vegetation of sedges, water birch (*Betula nigra*), alder (*Alnus* spp.), and willows (*Salix* spp.) to nonnative grasses. The losses of the native vegetation shrubs have a huge impact on native species. Many songbirds nest and feed in this streamside vegetation (Fig. 6).

Many dams and reservoirs built in the western U.S. and other arid regions are constructed primarily for water storage for irrigation. In many instances, that irrigation water is used to grow forage crops for livestock. These dams have many negative impacts on native species—for example, one study documented that riparian forests dominated by cottonwoods (*Populus* spp.) are declining due to disruptions in natural flood cycles and groundwater levels by dams, groundwater pumping and water diversions (Beauchamp et al., 2005). Changes in water temperatures and flows as a result of dam releases also negatively impacted desert dwelling native fish like humpback chub (*Gila cypha*) (USFWS, 2017).

The water stored in most western reservoirs is used primarily for irrigation of livestock forage crops.

A review by McAllister et al. (2014) of dams and their associated reservoirs impact freshwater biodiversity by blocking movement of migratory species up and down rivers, causing extirpation or extinction of genetically distinct stocks or species; changing turbidity/sediment levels to which species/ecosystems in the rivers affects species adapted to natural levels. Trapping silt in reservoirs deprives downstream deltas and estuaries of maintenance materials and nutrients that help make them productive ecosystems; filtering out of woody debris which provides habitat and sustains a food chain.

Dam management that diminishes or stops normal river flooding of these plains will impact diversity and fisheries. Changing the normal seasonal estuarine discharge which can reduce the supply of entrained nutrients, affecting the food chains that sustain fisheries in inland and estuarine deltas. Modifying water quality and flow patterns downstream.

Disease Transmission to Wild Animals

Many wildlife species, especially those closely related to domestic animals, often suffer from disease transmitted from domestic animals. Chronic Wasting Disease, Bovine Tuberculosis, and brucellosis found in wildlife all have origins with domestic animals. A well-documented relationship exists between population decline in wild bighorn sheep and the spread of pneumonia transmitted from domestic sheep (Schoenecker, 2004).

Fig. 6 Irrigated hay production for livestock is a major factor in the dewatering of rivers and streams, compromising aquatic ecosystems.

Predator Control

Another consequence of livestock production is the tendency to kill predators to protect domestic animals. Predators like wolves (*Canis lupus*), cougars (*Puma concolor*), coyotes (*Canis latrans*), and bears (*Ursus* spp.) are known as “top-down” species that shape ecosystems. Loss or reduction of these species can have significant ecosystem consequences. For instance, the presence of wolves in Yellowstone National Park is credited with reducing elk browsing on willows, and the rejuvenation of riparian areas (Ripple and Beschta, 2011).

Loss of large apex predators creates a release whereby mesopredators like coyote numbers increase. Bobcats (*Lynx rufus*), gray foxes (*Urocyon cinereoargenteus*), and Virginia opossums (*Didelphis virginiana*) were detected more often at sites occupied by pumas, whereas coyotes and raccoons (*Procyon lotor*) were detected less often. The detection probabilities of smaller mesopredators were related to coyotes, a dominant mesopredator (Wang et al., 2015).

Pest Control

Many native species are considered “pests” by livestock operators who seek to reduce or eliminate them from grazing lands. Prairie dogs (*Cynomys ludovicianus*), gophers (*Thomomys* spp.), ground squirrels (*Spermophilus* spp.), and other rodents are often the target of control efforts, sometimes to the point where native species may be endangered (Wuerthner, 1997).

Grasshoppers and other insects are controlled by poison (Shewchuk and Kerr, 1993). The loss of mammals or insects has impacts to desert ecosystems since these animals all are prey for other species from fish to birds to mammals.

Carbon Storage

Deserts have a low capacity for carbon storage; however, since arid regions cover about 47% of the earth’s land mass, they are thought to make up the world’s third-largest carbon sink on land. Nevertheless, new research suggests that some endorheic desert basins represent a vital carbon sink on the global scale, with a magnitude similar to deep ocean carbon burial (Li et al., 2017).

Vegetation Loss

Greater grazing pressure on the Mexican side of the International border provided a good comparison on how different livestock management policies can affect the land. For example, there was far less green vegetation on the heavily grazed Mexican side of the line (Berelev and Madsen, 2011).

A study of the Mexican-U.S. (Arizona) border found that the more heavily grazed Mexican desert was consistently warmer than the Arizona stations. The stations in Sonora (Mexico) warm at a statistically significantly faster pace than the stations in Arizona and the stations in Sonora reveal a significant increase in the diurnal temperature range during the summer season (Balling et al., 1998).

Higher temperatures near the surface of the soil can negatively affect insects like native bees and ants, reptiles like snakes, tortoises, and small mammals who move around close to the soil surface.

Climate Change

Although the overall number of domestic animals supported by desert ecosystems is low due to the limited productivity of these sites, domestic livestock has been identified as one the major contributors to global greenhouse gas emissions (GHG). While there are no numbers that break out just the domestic animals produced in desert regions, worldwide estimates suggest that domestic livestock may be contributing as much as 14% of all GHG emissions (Steinfeld, and Food and Agriculture Organization of the United Nations, and Livestock, Environment and Development (Firm), 2006). A more recent estimate put total global livestock contribution to GHG emissions at 23% (Reisinger and Clark, 2017).

Conclusions

Livestock production is one of the most significant influences on desert areas where it occurs, often leading to greater desertification and loss of biodiversity. When you consider the overall large landscape footprint and the cumulative effects of livestock production including the damage to riparian areas, forage competition with native wildlife, disease transfer, soil compaction, alteration of plant communities, predator control and dewatering of streams for irrigated forage production, it is easy to understand why some assert it is the greatest threat to our desert ecosystems.

Due to the natural aridity of desert landscapes, the ability to support livestock is limited. If a full accounting of both the economic and ecological costs impacts were done, it is difficult to justify continued livestock production in desert ecosystems.

Abstract

Mechanical recreation is a growing threat to our arid lands. Motorized and on-motorized Thrillcraft (machines used for entertainment and excitement) fragment wildlife habitat, disrupt and disturb native wildlife, spread weeds, compact soils, reduce water infiltration, trample or break vegetation, and displace other desert recreational users.

Thrillcraft is a term that collectively covers all means of mechanical recreational machines, including dirt bikes, four-wheelers, mountain bikes, electric mountain bikes, dune buggies, four-wheel-drive jeeps, and pickup trucks. In short, any mechanical device used to travel off highways and roads. Other collective names including ORV (Off-Road Vehicle), OHV (Off-Highway Vehicle) and ATVs (All Terrain Vehicles). All of these terms can and will be used interchangeably (Fig. 1).

No matter their name, the primary purpose of these machines is for traversing off highway trails, roads, or even where there are no designated trails. Although all of these machines have practical applications as necessary work-related transportation—you might have a four-wheel-drive pick up to traverse a snowy or muddy road or a four-wheeler to check on hay irrigation operations—all of these machines are used primarily for non-work recreation. The main goal of users is speed and the ability to overcome natural obstacles, i.e., thrills.

The research on the environmental impacts of Thrillcraft is limited. In many cases, research on the ecological effects of roads is used as a proxy since it is assumed that a trail has a similar impact on wildlife, soils, vegetation, and environmental processes (Trombulack and Frissell, 2000). Nevertheless, there are some well documented ecological and social impacts (Stokowski and LaPointe, 2000).

Their influence and effects have increased dramatically due to technological innovation. For instance, mountain bikers now use 29-in. tires which are quicker and allow riders to cover more distance, while the adaptation of electric motors to mountain bikes creating e-bikes also contributes to greater range and speed (<https://www.redbull.com/gb-en/polarising-mtb-tech>). The advent of electric Thrillcraft will only increase the use of these machines. For instance, Volkswagen is introducing an electric dune buggy (<https://www.foxnews.com/auto/volkswagen-is-bringing-back-the-dune-buggy>).

Fig. 1 Dune buggy in California desert. Photo by George Wuerthner.

The sales of these machines have increased significantly. In 1972 there were 5 million Thrillcraft registered in the United States that by 2004 had grown to 36 million (Patterson, 2007).

The use of these machines often results in significant environmental damage, including soil erosion, noise pollution, air pollution, fragmentation of wildlife habitat, loss of wilderness values, destruction of vegetation, social displacement of wildlife and social displacement of other recreationists.

In desert biomes where aridity and its limits challenge plant and animal species, the presence of Thrillcraft can have severe ecological impacts.

Weed Distribution

Weed seeds carried and spread by machines can “invade” new areas miles from other “infection” sites (Fig. 2). For instance, one study found that a single ATV might have as many as 2000 spotted knapweed seeds that were spread over a 10-mile area (Proescholdt, 2007).

Soil Impacts

Soil changes induced by Thrillcraft can change vegetation, facilitating invasion by exotic species (Greenberg et al., 1997). The primary effects of Thrillcraft use on soils and overall watershed function include altered soil structure (soil compaction in particular), destruction of soil crusts that stabilize soils, and soil erosion. By compacting soil, permeability (the rate at which water or air infiltrate soil) is decreased. The soil compact not only increases runoff effectively drying soils, exacerbating the already arid conditions in the desert, but it can also reduce root penetration, and affect vegetation (Ouren et al., 2007).

Under controlled conditions Adams et al. (1982) measured soil crust properties to determine how rapidly they were altered by passing vehicles. They determined that routes impacted by a single vehicle pass had soil strengths 5.3–28.4 kg/cm² greater than undisturbed soil, indicating that just a single pass can begin to affect soil strength. Mean soil strength on routes exposed to 10 and 20 passes was too high to measure.

In a rainfall simulation test, vehicle-use plots had about five times more runoff and 10–20 times greater sediment yield than adjacent unused plots (Iverson et al., 1981). Webb (1982) described the impact of motorcycles on desert soils and has measured compacted as deep as 1 m (Webb, 1982). Soil compaction limits water infiltration exacerbating the already arid conditions, and often increasing soil erosion.

Thrillcraft destruction of soil crusts which protect desert soils from erosion is a serious concern (Belnap, 2002).

Vegetation Impacts

Thrillcraft can also trample and break vegetation. The creation of dust also inhibits photosynthesis that can lead to a reduction in plant growth (Ouren et al., 2007; Fig. 3).

Fig. 2 The yellow vegetation in this photo are exotic weed species spread by the disturbance created by the ORV use. Photo by George Wuerthner.

Fig. 3 Dust from ORVs can inhibit photosynthesis in plants Photo by George Wuerthner.

One study of the time required for the full recovery of ecosystems degraded by Thrillcraft as well as other disturbances like live-stock grazing may be 3000 years (Lovich and Bainbridge, 1999).

Wildlife Impacts

ORV threatens many desert species. For instance, in the American Southwest destruction of habitat is a threat to the Sand Mountain blue butterfly (genus species) because its host plant the Kearny buckwheat (*Eriogonum nummularae*) is damaged by vehicle traffic.

A study of two plots in the Mojave Desert with desert tortoise (*Gopherus agassizii*) found the plot without Thrillcraft had 1.7 times more live plants, 3.9 times more plant cover, 3.9 times more desert tortoises and 4 times more active tortoise burrows than a nearby area used heavily by OHVs (Bury and Luckenbach, 2002).

Loud Thrillcraft noise caused hearing losses in sand lizards (*Uma scoparia*) and kangaroo rats (*Dipodomys deserti*) lasting for weeks after being exposed to less than 10 min of playback recordings of dune buggy sounds. The loud noise associated with some ORVs which can mimic thunder that causes the desert spadefoot toad (*Scaphiopus couchii*) to emerge prematurely from its hibernation to breed (Brattstrom and Bondello, 1983).

In a review of Thrillcraft impacts on biodiversity in the Algodones Dunes, a popular ORV recreation area in the California desert, found heavy Thrillcraft use virtually eliminated all native plants and animals (Luckenbach and Bury, 1983).

Other endangered species equally threatened by Thrillcraft include the Peninsula Ranges Bighorn sheep desert (*Ovis canadensis nelsoni*), desert tortoise, flat-tailed horned lizard (*Phrynosoma mcallii*), and Sonoran pronghorn (*Antilocapra americana sonoriensis*).

Zone of Influence

No matter what two factors magnify environmental impacts that Thrillcraft have on plants and wildlife. First, the linear distance that a machine can travel in a day is far greater than someone walking or riding a horse. The speed of mechanical Thrillcraft is also easier for wildlife to perceive, and this may account for the fact that elk (*Cervus canadensis*) detected both mountain bikes and ATVs at distances three times greater than detection of a hiker.

Roadless and trailless areas are critical to the survival of many desert species, especially those persecuted or those that are sensitive to human disturbance. Recent research has shown even the voice of hikers can influence the behavior of large predators like mountain lions (*Puma concolor*). In the Santa Cruz Mountains, researchers played tapes of humans talking and found that it reduced the feeding time of mountain lions and often led to the abandonment of kills. This disturbance also resulted in an increased kill rate of 36% (Smith et al., 2017). However, Thrillcraft are so pervasive that in southern Utah, some 99% of all public lands are within a mile of a motorized zone.

Mechanical access dramatically expands the potential impact of humans on wildlife. For instance, only 3% of the United States is more than 3 miles from a road. The US Forest Service alone has more than 643,737 km of road, which is enough to circle the globe more than 16 times. There are another 131,966 km of roads and "trails" for Bureau of Land Management lands where the bulk of all US desert ecosystems are located (https://www.fhwa.dot.gov/policy/2015cpr/chap12.cfm#_Toc463603405). This amount of existing access is then expanded further as Thrillcraft use the road and trail system—to create new routes and trails—often without any authority from the managing agencies.

Thrillcraft can influence and negatively impact the behavior of many wildlife species beyond the route traveled by a machine. Because human intrusions can effectively shrink the habitat used by wildlife, it's essential to consider the total influence, not just the narrow route that might be used by recreationalists.

Thrillcraft can influence wildlife in three ways: stress and disturbance, alteration of habitat, and collision/mortality (Quinn and Chernoff, 2010).

In a study of desert bighorn sheep researchers using ATVs deliberately harassed bighorns in a heavily used area and a lightly used area. The bighorns from the highly disturbed area responded with running flight 83% of the time, while the bighorns from the lightly used area only ran 46% of the time (King, 1985; Fig. 4).

In a controlled experiment, female elk were monitored in response to four types of recreational disturbance: all-terrain vehicle riding, mountain biking, hiking, and horseback riding. In one of the few comparative studies, the scientists recorded movement, flight responses, habitat selection, and security cover choices under disturbed and control conditions. Compared to control periods when elk spent most of their time feeding and resting, travel time increased in response to all recreational disturbance. Thrillcraft use eliciting the greatest increase in travel time, horseback riding resulting in the least (Wisdom et al., 2004; Naylor et al., 2009). Preisler et al. (2006) studied the response of elk to all-terrain vehicle use in a controlled-access area and found that once displaced from an area by human activity, and they habitually avoided those areas regardless of the attractiveness of the habitat within the zone of social influence.

Riparian areas are critical to many desert species. These thin green lines of vegetation supported by the presence of water are vital habitat to 70%–80% of all wildlife. Unfortunately, these riparian habitats, particularly dry streambeds, are often the choice route for Thrillcraft. For example, the Jeep Jamboree held in Moab Utah every year traverses a number of dry creek beds and wetlands. <https://jeepjamboreeusa.com/trip/southern-utah-adventure/>.

Social Factors

One of the problems with Thrillcraft is the outlaw culture that appears to dominate some members group. Compared to hikers, bird watchers, and other outdoor enthusiasts, Thrillcraft operators are willing to violate numerous restrictions and rule about where and when one can tear up the land.

This outlaw mentality idea applies to mountain bikers. ATVs, and other Thrillcraft. Trails and illegal use is common. For instance, in 2003 Forest Service Chief noted that “unmanaged” motorized recreation was responsible for more than 1600 km of unplanned roads and trails on Montana’s Lewis and Clark National Forest (Bosworth, 2003).

A study done on the Lewis and Clark National Forest found that there were at a minimum of 1348 unauthorized roads and trails extending for 1039 km (Meadows et al., 2008).

Demographics

One of the taunts thrown at those who advocate environmental restraint and protection for fragile lands is that they are “elitists.” However, demographic studies find that the majority of all Thrillcraft enthusiasts, including mountain bikers, are overwhelmingly male and between the ages of 20 and 40 (Fig. 5). They tend to be college educated and have above average incomes (Havlick, 2007). A 2004 New Hampshire study found that the average state ATV license holder owned two ATVs, one off road motorcycle, and spent more than \$3100 a year on clothing and related gear (Okrant and Goss, 2004).

Fig. 4 Desert bighorn sheep expend scarce energy running from ORVS in heavily used areas. Photo by George Wuerthner.

Fig. 5 The average Thrillcraft owner has average to above average income. The gear and equipment is expensive to buy and maintain. Photo by George Wuerthner.

Organizations that advocate for more Thrillcraft use and access like the Blue Ribbon Coalition tend to be supported in part by equipment manufacturers—ORV companies, mountain bike companies and the like (see history of Blue Ribbon Coalition here <https://sharetrails.org/aboutus/>).

As a consequence, they have a disproportional influence on public lands. For instance, the International Mountain Biking Association (IMBA) mission is to advocate for more trails and access (<https://www.imba.com/>). By contrast, I am not aware of even one full-time person working for any environmental group in the entire United States whose primary responsibility is to monitor and counter any ill-advised access. Indeed, IMBA brags that it has created more than 5000 new trails across the country.

Beyond just the ecological impacts, Thrillcraft use negatively impacts other recreational users of public lands. For instance, one Montana study found that 89% of hikers and 84% of horse riders found the presence of motorcycles was incompatible with their activities and impacted their experiences (Wuerthner, 2007).

Conclusions

Thrillcraft is a significant environmental impact on public and private lands in the United States, but their ecological impacts are greater in desert regions. The wide-open terrain and limited vegetation tend to favor cross country travel creating new trails. In addition, the growing population of cities near desert areas like Las Vegas, Phoenix, Tucson, and Salt Lake City has exacerbated this trend. These impacts negatively affect watersheds, vegetation, soils, wildlife, plant communities, and ecological processes. Restricting Thrillcraft to specially designated and concentrated areas could go a long way towards reducing these negative impacts.

Abstract

The Thar Desert lies in the westernmost part of India. It is characterized by low and erratic rainfall, low humidity, high solar radiations, strong winds and sparse vegetation. Livestock forms an integral part of the livelihoods of the people living in the Thar. Some of the districts in this region are characterized by a livestock density that is even higher than the human population density. The population in this region is also increasing at a rate faster than the national average. This has led to increased pressure on land for food security of the increasing population and fodder security for livestock. The forest land and the area under other land uses are being converted into arable lands. This can have serious implications on sustainability of the livelihoods and extent of poverty of the people in these districts. In this paper, we used Markov Chain analysis to see the direction of change in the land use pattern in the districts covered under the Western Dry Region. Among the various land use patterns, there was a high probability of the land under forest being diverted to cultivation. This could have serious implications in terms of desertification as all the nine districts covered under the Western Dry Region of Rajasthan are already very low in terms of forest area. We also examined the linkages between various human development indicators of these districts in light of the changing land use pattern in the districts. Using various development and desertification indicators, we worked out respective indices for the nine districts. We identified the districts which had high development indicators and drivers of desertification indicators.

Introduction

Salient Features of the Thar Desert Region

Rajasthan is the largest state in India in terms of area and 8th most populous state in the country, occupying around 5.7% of the country's population. According to 2011 Census, the population of Rajasthan is 68 million. Around 75% of the population lives in rural areas and only 66% of the total population of the state is literate. Being situated at the North Western part of the country, one of the main features of the state is the Aravali Ranges running across the state from South-west to North-east, dividing the state into two, with 60% of the area of the state lying in the northwest of Aravali and 40% in the southeast. The area in the North-west of the Aravali Ranges also inhabits the "The Great Indian Desert" or the Thar Desert (Fig. 1).

The moisture laden South-west monsoon winds are intercepted by the Aravali Ranges, placing the northwestern part of the state at the leeward side. This side receives very little rainfall and is mostly covered by desert. For efficient natural resource management, the Planning Commission of India has divided the country into 15 Agro-climatic Zones. Nine out of the 33 districts of Rajasthan come under the Western Dry Region. This zone covers most part of Thar Desert in Rajasthan. The nine districts of this Zone are Bikaner, Jaisalmer, Barmer, Jodhpur, Jhunjhunu, Churu, Jalore, Nagaur and Sikar which constitute the Thar Desert region of the state. Thar Desert is characterized by extreme summer and winter temperatures and very low rainfall.

The average temperature of this region varies from 45°C in May–June to 2°C in December–January. The annual rainfall in this region is around 400 mm with very high year to year variation. The cropping intensity or the percentage of area sown more than once in a given agricultural year is more in districts with high annual rainfall or high percentage of irrigated area. In six of the districts of the region, wells are accessed as the main source of irrigation. More than 90% of the irrigation in these districts is through wells. The forest cover in all the districts is much less than the optimum requirement of 33%. In three out of nine districts, the forest cover is <1% (Table 1). The region is at high risk of land degradation. Wind erosion is the major contributor of land degradation in this

Fig. 1 Map of the study area.

Table 1 Features of Thar Desert region.

Districts	Percent forest area	Annual rainfall (2015–16) in mm	Percent irrigated area	Cropping intensity	Sources of irrigation (%)		
					Canals	Wells	Other sources
Barmer	1.18	429.2	18.74	112	7.61	92.35	0.03

region. It affects 11,419,000 ha. Highly affected districts are Jaisalmer (2,753,000 ha), Bikaner (2,119,000 ha), Barmer (1,908,000 ha), Churu (1,346,000 ha) and Jodhpur (1,235,000 ha) (Maji et al., 2010). Considering the eco-fragile desert region, some of these characteristics are a cause of concern. For example, the forest area in these districts is very low, and, most of the irrigation is through wells, a cause of concern because ground water levels are already very low.

Importance of Livestock in Rajasthan

Land and livestock are the two basic means of livelihood for majority of the farmers in Rajasthan. Livestock rearing is a major economic activity in Rajasthan and makes significant contributions towards improving rural livelihood and reducing poverty, especially in the arid and semi-arid regions of the state (Das et al., 2014). Rajasthan possesses 11% of the total livestock of the country. The quantity and quality of livestock possessed is considered as an indicator for prosperity and social status of a family in the state. Livestock is particularly important in the state and more particularly in the drought prone Thar Desert region for several reasons. The agriculture in the state is marred by insufficient and erratic rainfall with frequent drought spells. Hence livestock has been very closely interwoven with agriculture as an integral part of the rural economy since ages. It is a source of nutrition to the households in terms of providing milk and meat, it provides added income to the households by selling of milk, the cow dung is dried and used as fuel in rural Rajasthan, selling of livestock during the events of crop failure or any other adverse financial conditions also helps the farmers to get immediate cash in times of need.

The composition of livestock population in Rajasthan has seen a major shift over the years (Table 2). The share of cattle in total livestock population has declined over the years while that of buffalo population has increased. While the percent of sheep has declined over the years in Rajasthan, the percent goat population has increased (Fig. 2).

The reasons for the increase in the goat population might be linked with increase in demand for chevon by consumers, easy management practices for goat over other livestock species, high remunerative price for chevon over other products, etc. (Soju and Meena, 2017). The camel population as well as its share in total livestock population has declined over the years. In an effort to save the camel population, it was named as the official state animal in 2014.

Fig. 2 Livestock production in the Thar Desert.

Thar Desert Region: The Human, Crop and Animal Dynamics

The Thar Desert is typically characterized by a low human population density which is lower than the livestock population density in most of the districts. Despite limitations of an arid environment, there is an increasing trend in the human and livestock population in the region. Between 1961 and 2011 census, human population has increased by >250% while between 1956 and 2012 census, the animal population has increased by about 125.2% (Moharana et al., 2016). The rise in human population has been higher in the drier districts of Bikaner, Barmer, and Jaisalmer (Table 3). Over the last ten years, the growth in the area under cultivation has also been very high in the districts of Bikaner, Jaisalmer and Jodhpur. So far, Jaisalmer had negligible area under irrigation but now, with the Indira Gandhi Canal Project covering some parts of the district, the scenario is changing at a greater pace (Pathak, 2015).

Materials and Methods

Direction of Land Use Change

The first order Markov chain approach was used to analyze the change in direction of land use. Central to Markov chain analysis is the estimation of the transitional probability matrix P . P_{ij} is the probability of transition from a land use i at time t to land use j at time $t + 1$. Elements of P are non-negative and each row sums to 1. In the matrix P , elements P_{ij} indicate the probability of switching of land use from i th use to j th use with the passage of time. The diagonal elements of the matrix measure the probability that the share of land use will be retained.

In the context of the current application, seven major land uses were considered. The average share of land to a particular use was considered to be a random variable which depends only on the past shares to that land use, which can be denoted algebraically as

$$E_{it} = \sum_{i=1}^r E_{it-1} * P_{ij} + e_{it} \quad (1)$$

where, E_{it} = share of land use from i th to j th use during the year t , E_{it-1} = share of land use from i th to j th use during the period $t - 1$, P_{ij} = Probability that the shares will shift from i th use to j th use, e_{it} = The error term which is statistically independent of E_{it-1} , t = Number of years considered for the analysis, r = Number of land uses considered.

The transitional probabilities P_{ij} which can be arranged in a $(c \times r)$ matrix, have the following properties:

$$0 \leq P_{ij} \leq 1 = 1 \quad \text{for all } i$$

There are several approaches to estimate the transitional probabilities of the Markov chain model such as unweighted restricted least squares, weighted restricted least squares, Bayesian maximum likelihood, unrestricted least squares. In the present study, minimum absolute deviations (MAD) estimation procedure was employed to estimate the transitional probabilities which minimize the sum of absolute deviations. For this purpose district wise land use data from 2007–08 to 2015–16 was taken. The conventional linear programming technique was used, as this satisfies the properties of transitional probabilities of non-negativity restrictions and row sum constraints in estimation (Varghese, 2011). Linear programming formulation is stated as

$$\text{Min } OP^* + Ie$$

Subject to,

$$XP^* + V = Y$$

Table 3 Human, crop and livestock dynamics in the Thar Desert region.

	Human population	Human population density	Increase in human population in the last decade (%)	Livestock population	Livestock population density	Area under cultivation	Growth in Area under cultivation in last 10 years
Barmer	2,603,751	92	32.52	5,366,732	189	1,893,964	0.22

$$GP^* = 1$$

$$P^* \geq 0$$

where, O = is the vector of zeroes, P^* = is the vector in which probability P_{ij} are arranged, I = is an apparently dimensioned vector of area, e = is a vector of absolute error (1 U 1), Y = is the vector of area under each land use, X = is the block diagonal matrix of lagged values of Y , V = is the vector of errors, G = is the grouping matrix to add the row elements of P arranged in P^* to unity.

Development Indicators

Development is a multidimensional concept and cannot be represented by a single indicator. In this paper, a combination of demographic, health and economic indicators was used to analyze development. A composite index was developed based on a combination of all these indicators. Similarly some indicators which act as drivers to desertification were identified. Composite indices for development and drivers to desertification were worked out using these indicators for all the nine districts. The indicators considered for development include decadal growth rate of population, percent female population, percent rural population, percent literacy, percent female literacy, percent households with access to electricity, percent households with access to clean drinking water, percent households with access to toilet facilities, infant mortality rate, under five mortality rate, sex ratio, work participation rate, per capita net district domestic product. Similarly, the indicators taken as drivers to desertification include cropping intensity, percent forest area, share of primary sector in employment, percent irrigation by well, livestock density and human population density.

The composite index developed by (Narain et al., 2009) was used. As the values of the variables have different measures, they are not suitable for combined analysis. Hence, the variables were transformed into z scores for the combined analysis. Then the indices were calculated using the formula

$$D_i = \bar{C} + 3S_i$$

where $\bar{C}$ = Mean of C_i , S_i = Standard deviation of C_i

Where

$$C_i = \left[\sum_{j=1}^k \left(\frac{R_{ij}}{(CV)_i} \right) \right]^{1/2}$$

where $R_{ij} = (Z_{ij} - Z_{oj})^2$, Z_{ij} = Z scores of each indicator, Z_{oj} = best value of each indicator, CV = Coefficient of variation.

The best value (Z_{oj}) was taken as the minimum standardized value or Z score for unfavorable indicators (e.g., infant mortality) which have a negative direction of impact and maximum standardized value or Z score for favorable indicators (e.g., Literacy) which have a positive direction of impact.

In order to find out the correlation between development and drivers of desertification, spearman's rank correlation coefficient was used.

$$r = 1 - \frac{6 \sum d^2}{n(n^2 - 1)}$$

where, r = spearman's rank correlation coefficient, d = difference between ranks, n = number of observations.

Results and Discussion

Changing Land Use Pattern

Changing direction of land use in all the nine districts of Thar Desert region of Rajasthan was worked out using Markov chain analysis. The transition probability matrices were obtained for each of the districts. From these matrices, the probability of shift in each of the land use were separated and are presented in the following tables. Table 4 shows the change in land under forest cover in the nine districts. The probability of retention of forest land by each of the district is given in bold. While Churu, Jaisalmer, Jhunjhunu and Sikar have 100% probability of retaining the forest land, Barmer, Bikaner and Jalore showed 0% probability of retention of land under forest cover. In Bikaner and Jalore, all the land under forest has the probability of being diverted to agricultural cultivation. The area under forest in Barmer, Bikaner and Jalore is 1%, 3% and 2% respectively which is very low as compared to the optimum level of 33%. When the forest land is diverted to agriculture and the land is tilled during windy summer season, the soil is left exposed to erosion by wind. Deforestation, especially in the deserts has adverse consequences. Lodh (2017) suggested that the expansion of the Thar Desert at the expense of cultivated and irrigated land (Indus basin) significantly impacts the summer monsoon precipitation over the entire Indian subcontinent, both locally and at regional scale.

All grazing land including permanent pastures and meadows come under the category of permanent pastures and other grazing land. The common grazing lands of villages are also included under this land use category. Community grazing lands are a common feature in the crop and livestock based livelihood systems of the Thar Desert. There has been drastic shrinkage and deterioration of

Table 4 Changing land under forest cover in Thar Desert.

Barmer	0.0000	1.0000	0.0000	0.0000	0.0000	0.0000	0.0000
Bikaner	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000	1.0000
Churu	1.0000	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000
Jaisalmer	1.0000	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000
Jalore	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000	1.0000
Jhunjhunu	1.0000	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000
Jodhpur	0.8288	0.0000	0.0000	0.0000	0.0000	0.0000	0.1712
Nagaur	0.6027	0.3813	0.0160	0.0000	0.0000	0.0000	0.0000
Sikar	1.0000	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000

such grazing lands due to encroachment and increasing human and livestock population leading to overgrazing and also putting them to other land use. The probability of retention of land under permanent pastures and other grazing lands by each of the districts is shown in bold. Bikaner, Jhunjhunu and Nagaur show 0% probability of retention of land under this land use (Table 5). In Nagaur and Jhunjhunu the land under permanent pastures has the probability of being put to crop cultivation. Jhunjhunu has high livestock and human population density. With increasing demand for food, more and more land under other uses is being diverted to agriculture. However, diverting land under pastures, could lead to increase in fodder insecurity among animals specially in districts with high livestock density. It is paradoxical that despite the livestock strength, the rangelands in the region are degraded and permanent pastures mostly devoid of grasses and shrubs (Kar, 2014).

Area under miscellaneous tree crops includes all cultivable land which is not included in net sown area. Land under trees, thatching grasses, bamboo bushes and other groves for fuel, etc. which are not included under "Orchards" are classified under this category. The probability of retention of land under miscellaneous tree crops and groves by each of the districts is shown in bold. The districts of Churu, Jalore, Nagaur and Sikar have zero probability of retention of land under this category (Table 6). In Churu, Jalore and Nagaur, the probability is of this land being diverted to cultivation.

Culturable waste land includes land once cultivated but which has not been cultivated for five years in succession. Fallow land on the other hand includes lands which were taken up for cultivation but has not been under cultivation for not <1 year and not

Sikar	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000	1.0000

>5 years. Studies have shown that land fallowing is beneficial to soil quality, crop production and overall long term sustainability (Cusimano et al., 2014). Wastelands can result from inherent/imposed disabilities such as by location, environment, chemical and physical properties of the soil or financial or management constraints. Thus, land under this category is vulnerable to severe degradation (Iyengar, 2003). The probability of retention of land under culturable waste land by each of the districts is shown in bold. Barmer and Jodhpur have zero probability of retention of land under culturable waste land (Table 7). In Barmer the probability of shift is in favor of net sown area. The culturable wastelands that are brought under cultivation are not very productive, have lower crop yield and may not be cultivated every year due to lack of appropriate technologies, crops, and irrigation facilities (Sharma, 2015). Community grazing land comprises mostly of culturable waste land and fallow land. The probability of retention of land under fallow land by each of the districts is shown in bold. Churu, Jaisalmer, Jhunjhunu, Jodhpur and Nagaur have zero probability of retention of fallow land and in all these districts the maximum probability is of the shift away from fallow land in favor of net sown area (Table 8). Any deviation away from culturable waste lands in favor of cultivation is a positive indication as land devoid of any vegetation, especially in the eco-fragile Thar Desert region makes it prone to land degradation due to wind erosion (Fig. 3).

Most of the districts in the Thar Desert region show a good probability of retention of land under net sown area. Barmer, Churu, Jhunjhunu and Sikar show >70% retention of area under cultivation (Table 9). The numbers in bold show the probability of retention of land under net sown area. Also noteworthy is the fact that >90% of irrigation in these districts is through wells. Increasing demand for food and fodder has led to intensification of agriculture in the Thar Desert region (Fig. 4).

Development and Desertification

“Desertification” is land degradation in arid, semi-arid, and dry sub-humid areas resulting from various factors, including climatic variations and human activities (Fig. 5).

It remains potentially the most threatening ecosystem change impacting the socio-economic conditions of millions of people living in the drylands, which account for a significant proportion of the Earth's land (Ambalam, 2014). In contrast to popular perceptions, desertification is not the natural expansion of existing deserts, but the degradation of land in arid, semi-arid, and dry sub-humid areas (Grainger et al., 2000). The chief drivers of desertification include deforestation, over cultivation, increasing population both human and livestock, excess grazing on the rangelands, industrialization and poor land use practices. Desertification is a major challenge in the drylands. Besides, people living in arid areas lag behind in terms of various welfare indicators like literacy, health, availability of basic facilities needed for a decent living etc. In this section, an attempt has been made to find out how the districts in the Thar Desert region fair in terms of various desertification and development drivers. Twelve indicators of

8	Jodhpur	0.78	8	0.71	3
9	Barmer	0.79	9	0.74	8

development and six indicators which are drivers to desertification were taken. Indices were worked out for both and the districts were ranked in terms of both the indices. This analysis has helped in identifying the most vulnerable districts in terms of both desertification and development drivers. For example, Bikaner, Churu and Jodhpur are the most developed districts, whereas Jalore, Barmer and Jaisalmer lag behind in terms of development indicators (Table 10). The districts which lag behind in development in the Thar Desert region are also those which have maximum area of desert. Similarly, the most vulnerable districts in terms of the drivers of desertification are Bikaner, Jhunjhunu and Sikar. Jhunjhunu and Sikar have the highest human population and livestock density. Food and fodder security becomes a major cause of concern in these districts. The cropping intensity is also highest in these two districts. Besides, 100% irrigation in these two districts is through wells. This results in depletion of ground water. According to (Narain and Kar, 2006), Jhunjhunu and Sikar are one of the most affected areas in terms of groundwater depletion where withdrawal exceeds annual replenishment through rainfall.

Key Findings for Policy Makers

Some of the results of this study from which policy suggestions can be drawn include

- The forest cover in the Thar Desert region is very low. Any shift away from forests in favor of agriculture would lead to further decline in the forest area.
- The land under permanent pastures and grazing land in some districts has the probability of being shifted to agriculture. This leads to increasing pressure on remaining pastures to meet the fodder security of the growing livestock population.

- iii. People practice mixed farming of crop and livestock in this area. There has been an increase in both human and livestock population in this area. This has increased pressure on the region's marginal land.
- iv. Considering the drivers of desertification, Bikaner, Jhunjhunu and Sikar are most vulnerable.
- v. Jalore, Barmer and Jaisalmer are the districts that lag the most in terms of development indicators.

Conclusions

Desertification and land degradation is a problem that needs urgent action in the Thar Desert region. The populations of humans and livestock are the major drivers of desertification in this region. Excess cultivation, over grazing, over use of ground water resources, and shifting land under various uses in favor of cultivation are the major pressure variables. There is an urgent need for policy interventions to ease the pressure on land in this fragile eco-region.

Abstract

As the effects of climate change advance, the development of renewable energy is a critical component in efforts to reduce greenhouse gas emissions to avoid the worst consequences of global warming. Deserts plants and animals are particularly vulnerable to increases temperatures and potentially decreasing rainfall. Adaptation strategies often rely on natural migration to latitudes and elevations that can support the life processes of these tough but fragile flora and fauna, otherwise they will become part of the current extinction crisis. In some cases, assisted migration may be necessary to help prevent extinction. Deserts are also desirable locations for utility scale solar and wind projects because of reliable and copious sun and wind. However, renewable energy must be carefully sited to avoid impacts to sensitive flora and fauna in order to be truly sustainable and conservative of the unique desert ecosystem processes.

Development of renewable energy is a critical component of efforts to reduce greenhouse gas emissions to avoid the worst consequences of global warming. Ambitious efforts are being adopted by regional governments to support rapid renewable energy development needed to meet emission reductions goals. Deserts plants and animals are particularly vulnerable to increasing temperatures and potentially decreasing rainfall. Adaptations strategies often rely on both natural and assisted migration to latitudes and elevations that can support the life processes of these tough but fragile flora and fauna, otherwise they will become part of the current extinction crisis.

With the need to transition to a fossil fuel free world, the southwestern deserts of North America are a magnet for solar energy development because they provide some of the best solar radiation in the world ([National Renewable Energy Lab, 2018](#)). California's deserts also have modest but important areas with consistently strong winds that have already been tapped to create significant wind energy areas ([National Renewable Energy Lab, 2013](#)). In addition, because of the unique geodynamics of the area, significant geothermal resources have been developed in several areas of the California deserts ([California Energy Commission, 2019](#)). With the need to quickly transition off of fossil fuels to avoid the worst impacts to the climate, these renewable energy resources have the added benefit of being close to one of the most significant electrical load centers in North America—coastal southern California with an estimated population in 2019 of almost 24 million people ([World Population Review, 2019](#)).

In the pursuit of incorporating renewable energy into national energy supplies, solar, wind and geothermal developers have focused great attention on the California deserts and floated many proposals to build vast industrial solar and wind facilities of various types. By May 2008, the Bureau of Land Management, a federal agency that manages over 100 million ha (248 million acres) of public lands primarily in the arid western part of the United States, had received 67 applications for large-scale solar developments, covering over 210,150 ha (519,293 acres) in the state of California alone. Thirty-eight percent of these applications were for photovoltaic systems. An additional 27% were solar parabolic trough projects, using mirrors to focus solar radiation on tubes to superheat liquids, which are then used to superheat water; resulting in steam to drive turbines that generate electricity (very much like typical power plants). The remaining 35% were a mixture of other types of solar technologies including power towers, solar hydrogen, solar thermal quad dishes, Sterling engines, and others. To date, over 15 large-scale solar projects have been approved in the California desert and of those over 10 have been constructed. Many of the early applications were speculative and ultimately withdrawn, while eight applications were rejected by the BLM because of conflicts with existing land-management plans and

conservation mandates. The active applications were initially checkerboarded throughout the California deserts, with some adjacent to existing transmission facilities while others would require significant new transmission lines to be built.

The focus on the desert southwest region was dubbed a “green rush” because of the rush to build industrial scale renewable energy projects to meet new renewable energy targets and obtain federal grant funding. However, because industrial development in these deserts which are one of the least ecologically fragmented and fragile areas left in the United States (Randall et al., 2010), development in this area raised significant concerns as well. To reduce CO₂ emissions, alternative renewable energy sources are essential to replace coal- and gas-burning power plants. But the rush for renewable energy development also must ensure that renewable energy is developed in a way that protects the unique and precious ecosystems of fragile desert ecosystems. It must also be properly sited to prevent blocking of wildlife connectivity corridors at the local, regional and landscape scales in order to keep the desert landscape connected. Preserving wildlife connectivity must also incorporate a variety of local species ranging from plants which primary move through seed and propagule dispersal, to less vagile terrestrial animals including ground dwelling insects, small mammals and reptiles to charismatic megafauna including bighorn sheep and coyotes.

How to balance these issues is complex, and critical to maintaining ecologically functional desert landscapes. Certainly, placing industrial solar as close to the load centers as possible is most efficient because it cuts down on transmission losses and provides energy where it is needed. Using existing disturbed lands in the deserts is another important factor to be seriously considered and perhaps mandated. Of course, renewable energy production on the already built environment (e.g., distributed solar on rooftops, parking lots, and urban brownfields), as well as increasing energy efficiencies is the least damaging and most efficient way to implement renewable energy and reduce our carbon footprint.

Deserts are Biologically Unique

From the biological perspective, there are many unique plants, animals, and habitats that are found on the lands that may also have prime solar resources. Some of these species are naturally rare and others have become threatened or endangered due to habitat loss, increased predation, and other factors. Agassiz’s desert tortoise (*Gopherus agassizii*), which is protected under federal and California Endangered Species Act laws due to their steeply declining populations are found throughout the Mojave Desert and inhabit areas with high solar insolation that have sandy soils and are generally flat to gently rolling hills. This type of habitat is often desirable for renewable energy projects as well as other types desert development including housing, industrial and military development. Habitat development results in desert tortoises being moved from project sites to adjacent areas that are home-ranges of other desert tortoises. Increasing local tortoise densities can exceed the carrying capacity of the landscape to support all the animals and tragically results in mortalities of both translocated and resident tortoises (Field et al., 2007). Both rare and endangered species increasingly rely on their remaining habitats to sustain them in an inhospitably arid landscape. Many resources are unique and rare in the desert landscape, like riparian areas and water sources that are essential for migrating birds and resident species alike. Fully inventorying and avoiding impacts to the rare and unique resources is key to any long-term sustainable development of industrial scale solar in the desert landscape.

In an effort to help steer solar development away from the most sensitive desert sites, data sets on areas that contain rare and unique biological resources were collected and assembled in order to inform decision-makers on the ecological and cultural values of the desert landscapes in California’s deserts. As those familiar with the desert already knew (Keeler-Wolf, 2003), these data sets confirmed that many of the areas of the California deserts already have significant existing unique resources, including landscape-scale wildlife connectivity corridors that are critical to allow for movement as climate change continues, where any type of development should be avoided. Many of these important areas also tend to be located in remote areas far from where energy is consumed. In contrast, rare and unique resources are far less common on previously disturbed lands and therefore efforts were made through planning processes to focus development options for large-scale renewable energy projects to lands that were already disturbed from prior land uses (farming, mining and other surface disturbing activities), near existing transmission and outside of crucial wildlife habitat and connectivity areas (including migration corridors).

However, as with any data-driven mapping exercise, the data are biased to what is known and where rare resources surveys have been conducted. Many areas of the deserts have not been well studied. Surveys are labor intensive and expensive, and few private or public land managers have the luxury of initiating much less completing comprehensive surveys. These data are often only collected when a change in land management (i.e. development of some sort) is proposed. Therefore, the paucity of data creates uncertainty about the status of the on-the-ground resources across large swaths of the desert landscapes.

Thoughtful consideration of how we will most efficiently and effectively achieve our carbon-reduction goals is clearly the path on which we must now embark. Combining distributed solar production and energy efficiency with careful placement of renewable energy projects can ensure our commitment to reducing CO₂ pollution while still respecting and preserving our deserts’ unique and world-class biodiversity.

Solar Energy

Desert landscapes seem like the perfect place for solar energy based on the abundant sunshine for which the deserts are renowned. Indeed, desert lands have been targeted for solar development particularly when the deserts are close to large cities (electrical loads) or existing transmission facilities that carry the power to loads centers.

Solar projects that are remotely located in undisturbed deserts all share common impacts on the terrestrial landscape: habitat fragmentation due to road and facility construction including fencing of the facility; conversion of intact landscapes into industrial facilities including in some cases complete removal of all vegetation and loss of stabilized soils. In addition, in order to get energy to the grid, off-site transmission infrastructure which requires numerous substations and hundreds of miles of roads, electrical towers and lines often need to be constructed. Poorly sited solar projects impact crucial wildlife connectivity corridors that are especially important as climate change pressures plants and animals to seek viable habitat elsewhere. Poorly sited solar projects have been constructed on lands critical to endangered or rare species.

The current technologies being used in desert landscapes are generally of three types, each of which successfully produces energy, and each impacting unique desert resources differently.

Photovoltaic (PV) Panels

Photovoltaic (PV) panels are a popular technology that have been implemented on large and small scales. The panels can be either stationary or on “trackers” that allow the panels to rotate on an east-west axis to maximize sun exposure. Popular panels are mostly manufactured as non-toxic crystalline silicon panels, but some are manufactured as cadmium-telluride panels, which is a potentially toxic material if not handled carefully. Crystalline silicon panels are the same type of panels deployed on roof-top and small-scale installations as well as large-scale utility installations indicating their flexibility of installation.

For large industrial scale PV installations in the desert, an unanticipated environmental issue arose in the deserts in California. Surveys for avian species were required as part of the environmental review for these projects, and those surveys detected typical desert avifauna, which would likely be displaced by the solar project. However, once solar PV projects were built, injuries and mortalities of ducks, grebes, pelicans and other waterbirds were documented during post-construction monitoring ([KCET-PBS So Cal, 2013](#)). From a distance, panels covering thousands of hectares appear lake-like from a human visual perspective, giving rise to the new category of research involving the hypothesis of a “lake effect.” The lake effect hypothesizes that utility-scale installations of PV panels may reflect and polarize light, even at night, making the PV field appear to be a water body. Migratory waterbirds in particular, when transiting across the desert, may be attracted to such installations, because the birds perceive them as a water body. The mortalities and injuries occur either from direct impact from crashing into the panels or, for certain waterbirds that require water in order to become airborne, the birds become stranded on the panels or on the adjacent ground after falling off the panels. Either way, this impact to the avifauna reliant on waterbodies was unanticipated and a point of current research.

Scientific research documents that polarized light attracts water-loving insects to oviposit on surfaces that polarize light but are not water, resulting in an ecological trap that causes complete reproductive failure for individuals ([Horváth et al., 2009](#)). PV panels produce polarized light which may be attracting birds as well as insects. Nonpolarizing white borders and white grates on the PV panels also reduces their attraction to water-loving insects ([Horváth et al., 2010](#)). However, this solution increases the actual footprint of the utility-scale PV project, causing a greater terrestrial footprint of disturbance.

Depending on the project, some desert utility-scale PV installations remove all above ground vegetation and smooth the landscape surface—by traditional grading or “cut and roll” treatment—prior to construction in order to facilitate installation of the PV panels. These treatments not only remove habitat, at minimum temporarily, but destabilizes desert soils by removing the crucial cryptobiotic soil crusts. Cryptobiotic soil crusts which are living symbiotic associations between cyanobacteria, lichens, algae and fungi, play a critical role in the ecology of arid regions in many deserts including in the southwestern United States. These cryptobiotic soil crusts create a protective surface layer that keeps underlying soil from wind and water erosion, retain water when precious precipitation occurs, provide safe sites for seed germination, increases soil fertility and are generally slow to regenerate once disturbed ([US Geological Survey, 2016](#)). Because these fragile soil crusts are often undetectable to the human eye, they are overlooked for the important ecological functions that they provide. Disturbances to these soil crusts from grading, “cut and roll,” and other soil disturbing activities at large-scale solar sites creates a cascade effect that destabilizes surface soils, causing increased erosion, loss of plant biomass, reduced soil fertility, reduced water retention and an increase in emissive particulates in the air, contributing to increased air pollution (PM₁₀ and _{2.5}).

At some industrial PV projects, vegetation has been allowed to regrow under the panels and is trimmed regularly to prevent coming in contact with the PV arrays themselves in order to reduce fire risk. Other PV projects prevent vegetation growth under the arrays.

Solar Thermal

Solar thermal projects superheat fluids that are typically run through a heat exchange facility to generate steam that runs turbines that generate electricity. Two main types of solar thermal projects have been implemented at an industrial scale include solar power towers and solar trough projects.

Power Towers

Solar power towers use reflective mirrors to focus the sun's radiation onto a collector at the top of a tower. The collector superheats fluids that ultimately drive turbines typically located at the base of the tower to generate electricity. The mirror field requires road construction along with the installation of the infrastructure. This type of construction creates the same fragmentation of the landscape as PV projects, and the same impacts to cryptobiotic soil crusts and resident animals.

Once in place, this technology poses a unique ecological impact to avian species—burning from the concentrated solar radiation flux. The sun's radiation is concentrated as it converges near the collector, and birds that fly into that concentrated solar flux can be impacted. Impacts range from feather singeing to direct mortality (Kagan et al., 2014). The concentrated solar flux also attracts insects into harm's way. Insects attracted to the intense light of the solar flux in turn attract insectivorous birds into harm's way as well, creating a “mega-trap” (Kagan et al., 2014).

During operation, the solar flux regularly needs to be refocused from the collector to another area for necessary collector repairs or to reduce the amount of radiation flowing into the system. The flux is typically redirected to standby points or arranged as a standby halo nearby the tower, which still threatens avifauna and insects that fly through or are attracted to the concentrated solar flux.

Numerous treatments have been proposed or implemented to try to divert avifauna from entering the solar flux area, but the diversion methods incur their own sets of impacts. From volatilizing a non-toxic grape extract (methyl anthranilate) distasteful to avifauna across the solar site, to the proposed use of acoustic devices that broadcast loud noises to scare away birds, to releasing trained predatory raptors to “patrol” the fence line of the power tower site and chase off birds, each of these treatments to reduce avian mortality at power tower installations are still experimental at this time but will require a full analysis of potential impacts to other species when implemented.

Solar Trough

Solar trough technology is one of the oldest solar thermal technologies. It utilizes a parabolic mirror that focuses the sun's radiation on a tube that contains a heat transfer fluid that is superheated from the focused radiation and circulates through the system to a heat exchanger. The heat exchanger engine then creates steam that drives turbines to produce electricity.

Solar trough technology requires laser-precise ground elevations in order for the heat transfer fluid in the tube to circulate freely through the parabolic mirror arrays and into the heat exchange system. These precise elevations require complete elimination of all vegetation and cryptobiotic soils in order to contour the ground to the technology's exacting specifications. No vegetation is allowed to regrow under the arrays. This technology can employ “wet cooling” that condenses the turbine-driving steam into water for reuse. But in the arid desert, the use of water to cool the steam is not prudent, so most all of the solar trough projects are required by local permitting agencies to only use “air cooling,” where the ambient outside temperature allows the turbine-driving steam to change state back to water.

Typically, the solar trough technology requires a series of ponds, where the fluid in the tube can be released for maintenance or other purposes. These ponds have been found to be impactful to avifauna, and particularly to water birds who try to land on them. While project permitting often requires netting of the ponds to prevent birds from landing on them, entanglements have been documented leading to bird mortalities (Kagan et al., 2014). Terrestrial animals have also been known to be trapped in ponds, despite fencing and netting.

Wind Energy

Wind energy has typically capitalized on the strong steady winds at specific locations, some of which are often located along the deserts' edges in passes and with consistent wind patterns. Traditionally large wind turbine arrays have been constructed to capture the wind energy by rotating turbine blades that drive the generation of electricity. Some experimental designs do not use turbine blades, but the vast majority of wind energy projects still employ varying blade configurations. The produced electricity, like solar-generated electricity, is collected at local substations and put onto the electrical grid via transmission lines.

Birds, bats and insects are vulnerable to being hit or affected by the turbine blades, causing injury and mortality. Impacts can occur all along the blade length, with rotational speed increasing along the length of the blade. Depending on the rotor size, wind speed and blade length, tips of the blades can reach 80 m per second (180 miles per hour). Wind turbines affect avian species differently. For example, large raptors that hunt by day are more vulnerable to impacts from wind turbines based on their flight behaviors. Coupled with raptors' relatively long lives, slow maturation and low reproductive rates, their populations are more affected by wind turbines than other types of birds (US Fish and Wildlife Service, 2018).

Bat injuries and mortalities have also been documented to occur from wind turbines. Direct strikes from turbines can cause injury and mortalities, as well as from barotrauma. Barotrauma is caused when bats encounter extreme changes in atmospheric pressure that occur near the blades of turbines. These air pressure changes can rupture air-containing structures such as lungs in mammals which causes internal bleeding and, potentially, death (Baerwald et al., 2008).

Insect mortalities are an emerging concern associated with wind turbines. Modeling of insect mortalities identifies vast numbers of insects are impacted by turbines (DLR, 2019); however, the implications of these vast numbers of mortalities remain unclear. Insect mortalities, as they collect on turbines blades, are known to significantly decrease the efficiency of the wind turbines by up to 50% (Corten and Veldkamp, 2001).

There are a number of actions that can be implemented in order to reduce the impacts to wildlife from wind farms. Newly designed or repowered wind farms can use careful “micro-siting” of each turbine on the landscape, which has been documented to greatly reduce the impacts to some raptors, other birds and bats. Wind turbine operation can also reduce impacts to birds and bats, by modifying the “cut-in” wind speed (the speed at which the turbine blades are allowed to start rotating and producing energy) above the wind speed at which birds or bats are able or likely to fly. Other experimental systems are currently being tried which detect and track large birds as they approach a wind farm and trigger a turbine shut down if the bird is projected to come into a turbine rotor-swept area.

Geothermal

Geothermal energy is a very location specific issue, and the terrestrial footprint is generally quite small in comparison to solar and wind energy projects. However, in the arid deserts, geothermal energy can impact the local water resources that plants and animals rely on for survival.

Energy Storage

Renewable energy production is an intermittent energy source. With solar energy relying on sunshine and not operating efficiently on cloudy days and not at night, and wind energy only operating when adequate wind is blowing, the need for energy storage has become of significant interest as we transition off of fossil fuels. Pumped storage projects, which rely on water flowing downgradient to generate electricity during times when renewable energy is not available and pumping the water upgradient when renewable energy is available, have become of interest even in arid parts of the desert. However, pumped storage projects use more energy than they generate (US Energy Information Administration, 2013), are not limited to using renewable energy to pump upgradient, and most often rely on open reservoirs to create their gradient differential. Open reservoirs are subject to significant evaporation in the deserts, coupled with the fact that initial water in the reservoirs is often procured from ground water, which can easily overdraft the local ancient aquifers. In addition to the documented net-energy-loss of pumped storage projects, the lack of binding requirements to use only renewable energy to pump upgradient and the significant use of groundwater makes pumped storage projects unsustainable in arid regions.

Threats From Industrialization

Habitat fragmentation remains a significant concern when industrial projects, including renewable energy, are implemented. Each facility requires fencing that inhibits terrestrial wildlife movement, although some projects try to minimize that impact by providing wildlife permeable fencing into project areas that will not harm wildlife. Careful siting of projects is requisite in order to avoid siting project in important wildlife movement corridors.

Energy produced at large-scale industrial renewable energy projects must also reach the electrical grid which requires new transmission lines and substations. Every transmission line requires a new road for construction and on-going maintenance. Often times these transmission lines are hundreds of miles (kilometers) long, further fragmenting habitat for biological organisms and losing an average of 5% of the energy they are carrying due to “line loss” (US Energy Information Administration, 2019). Transmission lines have also long been known to be a significant threat to avian species, particularly during nocturnal migration (US Geological Survey, 1978).

Typically, when projects are built on undisturbed desert lands, numerous new roads are required to be constructed to aid the actual project construction and ongoing operations. The new roads often remain for project maintenance purposes at solar sites, and at wind sites a roads are maintained to access each turbine. The new roads also provide vehicular access into new undisturbed desert lands. This additional habitat fragmentation creates new impacts including the introduction of new invasive species, edge effects and illegal trespass into formerly undisturbed lands.

Land Use Planning

Focused land use planning for renewable energy in deserts can benefit our transition to renewable energy and greatly limit the impacts to ecologically functional landscapes. For example, in 2016, a key planning process in California’s deserts—the Desert Renewable Energy and Conservation Plan (Desert Renewable Energy Conservation Plan, 2019)—crafted a plan across 10 million acres (over 4 million ha) of desert on federal public lands. The public lands planning allows for potential development of carefully

sited solar and wind energy on 388,000 acres (over 150,000 ha) in specific areas or zones close to existing transmission corridors, while providing greater conservation protections for over 4.2 million acres (over 1.7 million ha). The local jurisdictions including counties in this area have also undertaken planning to steer private lands development of large scale solar and wind projects to appropriate sites. This type of land use planning allows for streamlined transition to renewable energy near one of North America's largest energy loads while protecting one of the most intact ecosystems remaining in the continental United States.

Smart Renewable Energy Solutions

While industrial-scale renewable energy projects play a part in our transition to fossil fuel-free energy production, siting renewable energy projects in the already-built environment, close or in existing energy load centers has many benefits. These benefits include constructing projects on existing infrastructure near or on the site of energy consumption which eliminates most of the transmission line losses. It creates jobs in existing communities instead of remote areas in the desert that lack basic services. It also conserves the integrity of our ecologically intact and functional desert lands for future generations to enjoy.

Conclusion

While wide-open deserts near load centers will continue to appear attractive for renewable energy development, these fragile and easily damaged landscapes provide essential habitat and resources for rare and unique plants and animals that are adapted to live under ecological conditions that challenge most living things. Careful planning, based on the best available science, can identify appropriate areas for development of renewable energy in places with the least conflicts. Considerations for maintaining ecosystems need to include principles of conservation biology regarding maintaining large blocks of habitat that contain focal populations, maintaining well distributed populations across species ranges, minimizing habitat fragmentation, providing connectivity between habitat blocks and preserving peripheral population which are reservoirs of unique genetics. This conservation approach is critically important as climate change proceeds.

Abstract

More than 2800 species inhabit desert biome, of which many are threatened. Despite high biological diversity, deserts have largely been neglected in conservation plans. Species declines in deserts are mainly due to habitat loss and widespread hunting. We provide information on the protection coverage of deserts by global network of protected areas. We then broaden our discussion by including the subject of landscape connectivity. In this part, the necessity of incorporating connectivity in desert conservation plans is deliberated. In addition, relevant examples of desert species for which increasing connectivity is imperative for their persistence are provided. Finally, we introduce different modes of landscape connectivity in deserts including hydrological connectivity, landscape heterogeneity, and desert oases facilitating movement of a range of species from small invertebrates to large vertebrates. Hydrological connectivity is the result of water flow among water pools and is an important factor in persistence of aquatic species in deserts. Heterogeneous habitats both facilitate species movements and provide escape terrain from predators or human disturbances. Stopovers such as oases have great importance for migrating species crossing deserts.

Why We Need to Protect Deserts?

Until before the middle of 20th century, deserts were only valued as places for tourism and human explorations. However, developments of environmental concepts such as ecology, biodiversity conservation and human geography revealed other unknown values of deserts and resulted in introduction of eremology, the systematic study of deserts, their features and formation by Theodore Monod (founder in 1938 of IFAN, l'Institut Français d'Afrique Noire, Dakar, Sénégal). Today, deserts are recognized as areas with high biological and ecological values that may counterbalance with those of other biomes around the world. Despite low global coverage of around 17%, deserts are home to surprisingly high numbers of plant and animal species (Safriel et al., 2005). Along with xeric shrublands, desert areas are one of the top three richest biomes for terrestrial vertebrates harboring nearly 25% of the terrestrial vertebrates of the world (Mace et al., 2005).

Many desert-dwelling species have high conservation concern globally. Currently, more than 2800 species of plants and animals inhabit desert areas, of which many are threatened. With more than 1500 species, plants are the dominant group of organisms in deserts. Compared with animal groups, plants have the highest number of threatened species in each IUCN conservation category (Table 1). Among animal groups, reptiles and mammals account for the majority of species in deserts habitats (about 40% and 33.7%, respectively). Mammals make up the most threatened group of desert animals with the highest number of critically endangered, endangered and vulnerable species.

Large mammals constitute considerable proportions of threatened desert species. Many of desert herbivore species such as white antelope (*Addax nasomaculatus*), Saiga antelope (*Saiga tatarica*), Dama gazelle (*Nanger dama*), Slender-horned gazelle (*Gazella leptoceros*), Goitered gazelle (*Gazella subgutturosa*) and African wild ass (*Equus africanus*) are among the threatened species. In addition, the vulnerable cheetah (*Acinonyx jubatus*) and its critically endangered subspecies, the Asiatic cheetah (*A. j. venaticus*; Griffith, 1821) and also the critically endangered subpopulation of western African lion (*Panthera leo*) are the most prominent carnivores of desert biome. The Asiatic cheetah has disappeared across much of its historical range across central and southeast Asia. Only very small numbers of this large cat persist across deserts of central Iran as its last stronghold (Ahmadi et al., 2017). Birds, amphibians and insects are lesser common groups of threatened animals in desert habitats; however, they also include several species of high conservation concern such as hooded vulture (*Necrosyrtes monachus*, CR), Chilean woodstar hummingbird (*Eulidia yarrellii*, CR), Asian houbara bustard (*Chlamydotis macqueeni*, VU), *Telmatobius vilamensis* (the only CR species of amphibians

occurring in deserts), Sinai Baton Blue butterfly (*Pseudophilotes sinaicus*, CR) and Rugose Sand Grasshopper (*Sphingonotus rugosus*, EN). There are still many desert animal and plant species that have not been categorized into IUCN Red list due to lack of data (data deficient, DD) or have not been evaluated yet (NE). Therefore, if the required data are available for detailed evaluations, the number of threatened animal and plant species in desert biome may increase.

Deserts with significantly high numbers of endemic threatened species have the potential to be qualified as biodiversity hotspots. However, these habitats have largely been neglected as biodiversity hotspots (Durant et al., 2012) and or priority conservation areas due to their low biological productivity (Durant et al., 2014). Species declines in deserts are mainly due to habitat loss and widespread hunting (Safriel et al., 2005). An example is the Horn of Africa with more than 2500 endemic species of birds, mammals and plants. Nearly 95% of species' habitats in this region have been degraded by human activities and without proper protection, ongoing human threats will increasingly result in loss of many species not found elsewhere in the world. To avert biodiversity loss in this region, and for deserts in general, it is necessary to expand conservation actions across this biome.

Protection Coverage of Deserts

Protected areas (Hereafter PAs) coverage for desert biome is provided by the World Database on Protected Areas (WDPA). The database includes six IUCN management categories and three categories of Not reported, Not assigned, and Not applicable (Fig. 1) (UNEP-WCMC, 2016) (Ia: Strict nature reserve, Ib: wilderness areas, II: National park, III: Natural monument and Natural feature, Habitat management area and Species management area, VI: Protected landscape and Protected seascape). Assessments that considered all these categories, provided close estimations for desert protection level ranging from 9% to 11% (Brooks et al., 2004; UNEP-WCMC, 2008; Chape et al., 2008; Jenkins and Joppa, 2009). However, when only strictly PAs are considered (IUCN categories I-IV), protection coverage for desert biome drops to 4.2% (Jenkins and Joppa, 2009). Unlike warm deserts, the protection coverage of cold deserts has rarely been considered. Chape et al. (2008) estimated a protection coverage of 8% for cold deserts using all the data in WDPA. Based on this assessment, cold and warm deserts together are among the habitats with relatively high percentage of area protected (18% coverage). In terms of biogeographic realms, highest protection for desert biome is provided by the network of PAs in Nearctic region (mostly in North America) followed by Afrotropic realm (mostly in Africa) (Brooks et al., 2004; Jenkins and Joppa, 2009).

Importance of Connectivity for Desert Species

Distribution of Desert Species

Species living in desert regions usually display patchy and isolated distribution due to scarcity of required resources (Murphy et al., 2012). This pattern of distribution has resulted in many desert species distributed across large areas, but with low population densities (Kahal, 2015). Although the comparably large size of desert PAs (Chape et al., 2008) may support proportions of suitable habitats and resources, they may not be large enough to cover the full range of widely distributed habitats for species throughout the year. This is particularly true for migratory and wide-ranging species of herbivores and carnivores inhabiting desert habitats. Habitat ranges of these species usually span large areas with an order of magnitude larger than the size of individual PAs. A notable example is the migratory wild ass (*Equus hemionus*) that has been documented to travel across areas of more than 80,000 km² in search of resources in Gobi Desert.

Fig. 1 Global distribution of desert and xeric shrublands across continents and within the network of PAs. Colored polygons indicate proportion of desert biome and PAs overlap in continents of America (gray polygons), Africa (green polygons), Asia (yellow polygons) and Australia (dark blue). The PAs include all six categories of IUCN and three categories of Not Reported, Not Assigned and Not Applicable. Spatial data on desert biome and PAs in each continent were respectively obtained from the Nature Conservancy (<http://maps.tnc.org>) and WDPA.org.

Anthropogenic Impacts on Desert Species

Human developments such as roads, agricultural lands and urbanization have largely altered desert landscapes across the world. Habitat loss and fragmentation as adverse impacts of human activities increasingly isolate already disconnected desert habitats and populations. Transportation developments increase risk of species road collisions (Lovari et al., 2007) and may act as movement barriers reducing species ability to move among populations and habitats (Frair et al., 2008).

Human activities may pose a great conservation challenge in desert areas as some of the most threatened migratory (Berger, 2004) and wide-ranging species in the world live in these habitats. High movement ability and wide habitat requirements make large mammal species particularly vulnerable to anthropogenic interventions in deserts. As an example, monitoring movements of Mongolian gazelles (*Procapra gutturosa*) and Asiatic wild ass (*Equus hemionus*) in Gobi Desert revealed avoidance of both ungulates from crossing railroads and fences in the border of China and Mongolia (Ito et al., 2013). Large carnivores are other group of wide-ranging desert species impacted by human interventions in these habitats (see Dickson et al., 2013; Ahmadi et al., 2017; McClure et al., 2017). An important example of these species is the critically endangered Asiatic Cheetah (*Acinonyx jubatus venaticus*) inhabiting central Iran. Reduction in density of prey within Iranian PAs (Ziaie, 1996) has forced populations of this large cat to move across large desert areas outside the PAs (Farhadinia et al., 2013). Nearly all core habitats for the species are surrounded by roads (Ahmadi et al., 2017) and the individuals have to cross these constructions to reach other habitats. Currently, road collision is a major cause of decline of Asiatic Cheetah population and a serious threat to survival of this carnivore (Farhadinia et al., 2017). In addition to large species, impacts of human developments on habitat availability and connectivity have also been documented for smaller desert species. For example, Kadaba et al. (2013) showed the impact of wind and solar energy facilities on 13 of the 16 critical corridors identified for movements of the desert kit fox (*Vulpes macrotis arsipus*) in California.

Concerns over the adverse impacts of human developments on desert species also exist for species with metapopulation structure. Metapopulation is a set of locally distributed populations connected by dispersal (Hanski and Simberloff, 1997). These movements play a critical role in maintaining the viability of metapopulations. By providing recolonization opportunity, dispersal helps the recovery of locally extinct subpopulations. Movement of individuals also helps in increasing genetic diversity and prevents adverse impacts of inbreeding. In deserts, metapopulation structure is common for species in mountains that are surrounded by the desert matrix such as Black bear (*Ursus americanus*) populations restricted to highland forested woodlands in the Chihuahuan desert (Pelton, 2003) and bighorn sheep in the desert mountains of southern California (Epps, 2004). Unsuitable environmental conditions in the desert matrix may limit movements of these species; however, they are not complete barriers as have been crossed by individuals (Epps, 2004; Onorato et al., 2004). Creation of barriers and an inhospitable matrix may result in complete isolation

of local populations of black bear and bighorn sheep. For these species, conserving the least impacted movement pathways within the matrix could contribute to maintain movements among metapopulations.

Climate Change and Desert Habitat Connectivity

Since climate is the main environmental factor in shaping deserts, these habitats represent high vulnerability to climate change (Yang et al., 2009). Climate change is expected to put already warm and dry deserts in more extreme conditions either directly through the effects on thermal and water stress or indirectly through impacts on quantity and distribution of habitat resources (Iknayan and Beissinger, 2018). Desert species may respond to direct impact of climate change by shifting their range to areas where suitable habitat conditions are available. Physiological adaptations may enable desert species to withstand unsuitable environmental conditions. However, if changes in climatic factors exceed species physiological tolerance and reduce survival, range shifts are expected (Moses et al., 2012).

A major concern is climate change impacts to PAs. With respect to the high velocity of climate change projected for desert biome (Loarie et al., 2009), it is expected that change in climatic conditions occur across large areas greater than the size of individual PAs. Hence, current desert PAs may change to unsuitable habitats that are no longer efficient for species within them. For instance, future projections estimated a 75% reduction in efficiency of central Iranian desert PAs to conserve goitered gazelle (*Gazella subgutturosa*) by 2070 (Malakoutikhah et al., in press; under review manuscript). In addition, high velocity of climate change in deserts means that the nearest suitable habitats in future may be considerable distances away from the current habitats. Under such circumstances, survival of desert species largely depends on their ability to move and find suitable habitats elsewhere. This highlights the importance of connecting current PAs to suitable habitat areas in future as the most effective strategy for species persistence under future climate change (Heller and Zavaleta, 2009). For some desert species, however, the distance to the nearest future suitable areas may be beyond species dispersal ability. For example, future projections for the scimitar-horned-oryx (*Oryx dammah*) showed that the species needs to travel thousands of kilometers from Sahel to nearest suitable habitat in Kalahari Desert, which is not possible considering the species movement ability (Thuiller et al., 2006). In these cases, assisted migration could be an effective approach to conserve this species (Hunter, 2007).

Increasing habitat connectivity also helps in reducing the synergic impacts of land use and climate change on species. In many cases, species tracking suitable habitats have to cross inhospitable landscapes dominated by human land uses (Lawler et al., 2009). In the absence of connectivity among landscape patches, many species may not be able to escape from unsuitable habitats and will be seriously threatened by climate change (Baranyi et al., 2011). For instance, climate change has caused desert bighorn sheep to lose proportions of their original range during the past few years (Epps et al., 2004). Human land uses on the other hand, increasingly contribute to fragmentation of the species habitats and isolation of the populations (Kahal, 2015). To survive negative impacts of climate change, populations of bighorn sheep must move to access habitats at higher elevations. However, they are most likely encountering human barriers in the matrix. Thus, conserving the most permeable part of the Californian desert that facilitate movements of big-horn individuals is critical for persistence of this ungulate in a changing climate.

Currently, only 6.7% of the desert biome is covered by protected connected habitats (Saura et al., 2017). It is expected that habitat connectivity will be degraded in desert areas as a result of climate change. Therefore, as an adaptive conservation approach; it is a priority to prevent loss of habitat connectivity in desert areas under climate change.

Landscape Connectivity in Deserts

Landscape connectivity is defined as the ability of a landscape in facilitating or impeding species movements (Taylor et al., 1993). Structural and functional connectivity are two components of landscape connectivity (Tischendorf and Fahrig, 2000). Structural connectivity describes physical features in a landscape such as vegetation, topography and hydrology that facilitate species movements (Rudnick et al., 2012). Functional connectivity on the other hand, describes movement of species or gene flow across a landscape (Rudnick et al., 2012).

Structural and functional connectivity are important for movement of desert species among habitat patches. In general, natural patchiness and isolation of habitats limit the structural connectivity in desert habitats. However, this component plays a key role in survival of species with low dispersal ability such as those inhabiting mountains and isolated freshwater pools in deserts. Functional connectivity on the other hand, is usually observed for large desert species with high mobility. Although for these species patches of suitable habitat may be located within large distances; high dispersal ability enables them to access distant isolated habitats.

Hydrological Connectivity

The most common type of structural connectivity in deserts is hydrological connectivity. Water resources harbors high levels of biodiversity in deserts and acts as micro-hotspots for desert biodiversity (Vale et al., 2015). In deserts, due to variability in climate, water pools remain isolated most of the year, which could have adverse impacts on species survival. Hydrological connectivity is the result of water flow among water pools and is an important factor in persistence of aquatic species in deserts (Vale et al., 2015). This type of structural connectivity in deserts is provided for limited periods of time; when freshwater pools are connected through floods resulting from precipitation. In addition to climate change (Woodward et al., 2010), anthropogenic factors such as overexploitation of desert water resources, and intentional alternation of water flow are other major contributors reducing fresh water connectivity in

these ecosystems (Vorosmarty et al., 2010). Another type of hydrological connectivity in deserts is the connections provided by permanent source of flowing water such as rivers. An example of such connection is the Nile River corridor. In addition to facilitating dispersal of aquatic species, by providing vegetation and riparian habitats, this corridor also allows migration of a range of terrestrial species along its path (Brito et al., 2014).

Deserts Landscape Heterogeneity and Connectivity

Habitat heterogeneity refers to the diversity of physical features such as topography in a landscape. Landscape heterogeneity constitutes the structural component of landscape connectivity as it determines the amount and continuity of available habitats to species (Taylor et al., 2006). Because of dominance of low-relief areas, deserts have very low habitat heterogeneity. However, high topographic complexity and hence heterogeneity exist in mountainous parts of deserts. One important function of heterogeneous landscapes in desert ecosystems is to assist movements of species particularly those living in desert mountains. Similar to many desert species, mountain species in deserts display spatially fragmented distribution. Adaptation to especial climatic or environmental conditions has narrowed the climatic niche of these species. Thus, environmental conditions in the desert matrix could act as major barrier to movement of mountain species. For these species, mountainous habitats function as key connectivity habitats in providing structural connectivity and decreasing negative impacts of isolation on populations. Furthermore, heterogeneous habitats allow species to access to larger climatically suitable areas in response to climate change.

Apart from facilitating movements, heterogeneous habitats may also provide the opportunity to escape from predators or human disturbances. For example, bighorn sheep select a variety of connectivity habitats such as plains, canyon bottoms, and washes to move between mountains (Penrod et al., 2012). However, the species main preference is to move along ridgetops of mountain hills or open habitats in proximity to escape terrains where higher safety is provided (Penrod et al., 2012). Likewise, topographically complex habitats in deserts play an important role in maintaining movements of large desert carnivores. Wide home range size along with vast areas of open space in deserts make large carnivores rather conspicuous. In addition, availability of prey species has been documented to be high across rugged habitats (Dickson et al., 2013; McClure et al., 2017; Ahmadi et al., 2017). For these species, rugged terrains provide enough security and stalking cover helping individuals to maintain movements across topographically complex landscapes (Beier et al., 1995; Stoner et al., 2008).

Role of Desert Oases in Maintaining Connectivity

Long-distance migrations of species cannot usually be fulfilled if stopover sites are not available along their migration routes. This is particularly challenging for migration pathways crossing desert areas as harsh habitat conditions in deserts can be seriously threatening. Long-distance migratory species crossing desert areas require habitat patches within their migration routes to rest and recover their energy stores. In desert areas, small isolated oases formed along water resources are critical stopover sites providing resting and foraging opportunities (Williams et al., 2006). Stopovers are of particular importance for birds that travel long distances, crossing unsuitable areas. For instance, for neotropical birds traveling thousands of kilometers yearly between breeding and wintering habitats in North America and tropics, xeroriparian habitats in Sonoran deserts, southwest Arizona, are important stopovers during spring migration (Hardy et al., 2004). Likewise, many migratory passerines use riparian habitats in Sahara Desert of Africa as their stopover while traveling to other places (Bairlein, 1988).

Although oases occupy small proportion of desert areas, they are critical in maintaining the integrity of migration movements. These habitats could function as stepping stones (Hendricks, 2011) and help in maintaining connectivity among desert areas or deserts and other habitats at larger spatial scales. With respect to the role of these small and isolated habitats, their degradation (by hydrological manipulation, over-harvesting and conversion of habitats, etc.; National Research Council, 2002) could lead to disruption of long-distance species migrations. Therefore, protection of oases should be a priority for conservation of migratory species crossing desert habitats.

Conclusion

Deserts are known as one of the most biodiverse biomes with many species of high conservation value. Some deserts harbor considerably large numbers of unique species that are not found elsewhere and have the potential to function as biodiversity hotspots. However, little conservation efforts have been dedicated to properly conserve desert habitats and species. Currently, about 9%–11% and 6.7% of desert habitats are respectively covered by PAs and connected habitats. This low level of habitat protection could be challenging with respect to ongoing anthropogenic threats such as habitat loss and fragmentation, overhunting, and climate change. As a result of climate change, many desert species need to shift their current ranges resulting in reduction of PAs' efficiency in future. In addition, expansion of anthropogenic developments may be a serious threat to desert species as they can destroy and interrupt potentially suitable habitats and connectivity areas. Under this condition, inclusion of new conservation sites, expansion of current PAs based on species future distribution and maintaining connectivity among them are effective conservation efforts for future protection of this fragile ecosystem in a changing climate.

Abstract

Deserts harbor unique natural and cultural heritage that is found nowhere else in the world. However, threats to these heritage resources are rising due to increasing levels of accessibility, human population and exploitation of natural resources. Thus, new alternative tools are needed to safeguard these fragile environments. In this respect, ecotourism has the potential to preserve the desert biome while supporting local cultures, traditional livelihoods and sustainable development. Deserts display many opportunities to promote ecotourism, such as unique biodiversity protected by large national parks and reserves, geological features, archeological and historical sites evidencing past cultures, and a great variety of ethnic groups and costumes. Still, protection of desert heritage is challenged in many countries due to low levels of security, development and political stability. Ecotourism generates a plethora of environmental, economic and socialcultural impacts that need to be considered when developing tourist activities in desert environments. However, ecotourism should not be envisaged as a panacea for all the challenging impacts that deserts are facing, but it can offer a sustainable tool to contribute positively to the wellbeing of people and communities living within deserts. Ultimately, desert ecotourism can contribute to the 2030 agenda of the United Nations for the Sustainable Development Goals and the conservation and management of desert heritage.

Introduction

Ecotourism has been suggested as a tool for the conservation and management of deserts' natural and cultural heritage. As one of the fastest growing sectors of global tourism industry, ecotourism has a potential to serve as an environmentally, socioculturally and economically viable option for promoting sustainable development in the desert biome. Many factors provide opportunities to develop ecotourism in deserts, which need to be carefully considered for both nature conservation goals and local socioeconomic wellbeing. For this article, we start by contextualizing ecotourism and its research in deserts, and then describe possible attractions and constraints exhibited by deserts to develop ecotourism. We conclude with a discussion of the potential positive and negative impacts that ecotourism may derive on different desert facets.

Brief History of Ecotourism and Its Research on Deserts

The relationship between the environment and tourism has interested conservation researchers and managers for a long-time (Wagar, 1964; Budowski, 1976). The term ecotourism became popular in the 1990s, when scholars started raising interest in the conflicts and potential solutions and symbiotic relations between tourism and the natural environment (see Ceballos-Lascurain, 1996). Multiple definitions of the term have been proposed and revised since then. In general, ecotourism refers to tourism in natural environments involving a conservation element, environmental education components, and benefit sharing with local communities (Fennell, 2001). Some scholars (Weaver, 2001a; Fennell, 2015) consider that ecotourism needs to address the following factors:

- (1) be developed at small scales, for example, in typically low-density groups of travelers;
- (2) foster behaviors that help preserve local biodiversity and habitats, particularly by potentiating environmental awareness and learning experiences among tourists, and with local communities, the importance of biodiversity preservation through environmental education;
- (3) contribute economically to the preservation, maintenance, and enhancement of biodiversity and habitats;
- (4) respect the integrity of host communities (local beliefs and livelihoods) while committing to promote local culture and ensuring folklore maintenance (i.e., orientated to locals);
- (5) generate net positive incentives to the local economies and the well-being of communities (i.e., improving the welfare of local people) sufficient to make them value and protect the surrounding wildlife heritage as an income source;
- (6) balance the biocentric and anthropocentric views to ensure long-term sustainability of projects;
- (7) be moderately commercialized.

Therefore, developing ecotourism is not a simple task, and planners, managers, and policy makers need to understand and contextualize these dimensions if they want to achieve sustainable development in tourism.

Being the fastest growing segment of the tourism industry, ecotourism is estimated to generate annual revenues of more than \$28.8 billion for developing countries (Kirkby et al., 2011). This is 34% more than what is spent annually by governments, private donors and official aid agencies in global conservation projects (Waldron et al., 2013), and, for example, 44% of the value needed to cover the global annual costs of protecting and managing Important Bird Areas (McCarthy et al., 2012). Yet, there are no reliable financial figures on ecotourism for specific biomes, such as deserts (UNEP, 2006a). Different types of ecotourists contribute to these expenditures and market segmentation divides them into “hard” and “soft” ecotourists according to their motivations, attitudes, and behaviors. Hard ecotourists are considered as having strong biocentric attitudes and commitments to environmental issues, they desire deep and meaningful interactions with the environment, travel in small groups, and search for physically challenging experiences requiring few or no tourism supporting infrastructures, while soft ecotourists exhibit the opposite traits in the ecotourism continuum. As such, the hard ecotourist may spend more time with local communities to understand their relationships with nature, whereas the soft ecotourist opts for experiences of shorter duration (Weaver, 2001a). Market segmentation is, therefore, important also for ecotourism developers as it helps to manage the natural resources and their utilization. These strategies help maximize the economic and environmental contributions of ecotourism to achieve the United Nations Sustainable Development Goals (UN-SDGs; UNWTO and UNDP, 2017), particularly in alleviating poverty, providing decent work and economic growth for all, promoting gender equality (reducing inequalities), protecting desert life, and establishing strong partnerships between the business, local communities, governments, academia, and NGOs.

The desert biome is still underrepresented in the general literature of ecotourism research (Santarém and Paiva, 2015). Deserts are home to 6% of the world’s human population, mostly poor and marginalized (UNDP, 2011). They have been mostly neglected for conservation and development funding schemes (Waldron et al., 2013). Furthermore, they contain some of the most threatened biodiversity, fragile environments, and vulnerable cultures in the world (UNEP, 2006b; Brito et al., 2014, 2016, 2018). As such, ecotourism constitutes a complementary step to preserve the natural and cultural heritage of deserts while potentially improving local livelihoods. Additional efforts are needed to design desert ecotourism products that translate into sustainable development in tourism.

Potentials and Constraints of Deserts to Develop Ecotourism

Deserts exhibit a plethora of potential attraction elements motivating tourists to visit these areas but also involve several constraints for ecotourism development (Table 1). Both aspects are crucial to consider, and they should take into account the pressures that ecotourism can create on the environment and the existing economic and sociocultural uses of the desert biome (UNEP, 2006b).

Desert Attraction Elements for Ecotourism Development

Most deserts and arid regions classify as being among the last wild biomes on Earth (Watson et al., 2018), which offers excellent opportunities for ecotourists seeking “last-chance-to-see” places (Lemelin et al., 2012) that are considered as wilderness areas (Saarinen, 2018). Deserts are also characterized by the high “visibility factor” that increases the likelihood of successful wildlife

encounters (Weaver, 2001b), including unparalleled natural sceneries and geological features, especially by ecotourists focusing on nonliving natural phenomena (Weaver, 2001a).

Natural features

Deserts display remarkable landscape features highly attractive for ecotourism (Fig. 1). They are considered natural laboratories for investigating the history of Earth, as extreme aridity and sparse vegetation provide large areas of exposed bedrock materials showing the record of geological processes operating for millions of years. Deserts provide a large number of paleontological findings (UNEP, 2006b), with the most noteworthy examples including:

- Badland terrains of the Gobi Desert, where 65 million years-old dinosaurs and mammal fossils were unraveled;
- Ténéré Desert in Niger, where excavations revealed 25 tons of dinosaur fossils;
- Pisco Basin in Peru, where stratigraphic sequences of Miocene to Pliocene rocks show assemblages of fossil marine mammals;
- Colorado Desert in California (United States), where one of the most complete records of late Cenozoic land mammals for North America can be found.

One of the most iconic landscape features of deserts is sand dunes. Among them, the Skeleton Coast in Namibia, the 168,350 km² of parallel dunes of the Simpson Desert in Australia, and the world highest sand dune in Atacama Desert, Chile (Cerro Medanos at 2100 m) are the most remarkable. Sand dunes provide scenic settings that provoke strong emotional connections to nature, offer relief from high-stress daily life of urbanized people, and provide exceptional opportunities for experiencing solitude and tranquility. Other prominent landscape features of deserts are high-altitude mountains. For example, the Tibesti mountains in Chad, the Al Hajar Mountain in Oman, or the Kerman mountains in Iran all rise above 3000 m (UNEP, 2006b). Isolated rock formations that rise abruptly from a surrounding plain, known as island-mountain or inselberg, are also highly attractive, and an iconic example is the Uluru in the Northern Territory (Australia).

Indeed, deserts contain spectacular geological features of potential interest for ecotourists. A few examples from around the globe are as follows:

- Volcanic cones, such as the Trou au Natron and Emi Koussi (2450 and 3445 m elevation) in the Saharan Chad;
- Meteorite impact craters, such as the Wabar Craters in Saudi Arabia;
- Rock canyons (deep cleft between escarpments or cliffs resulting from weathering and the erosive activity of a river over geologic timescales), such as the majestic 450-km long and 1.5-km deep Grand Canyon (United States) or the Iherir-Imirhou valley in the Tassili n'Ajjer (Algeria);
- Rock arches formed by wind and water erosion processes, such as the Aloha Arch in the Saharan Chad, the Jabal Umm Fruth Bridge in the Wadi Rum of Jordan, or the Arches National Park (United States);
- Desert potholes (shallow puddles or deep pools that collect precipitation from small catchments), such as in the Colorado Plateau (United States);
- Eolian *yardang* landforms (massive corrugated ridges), such as in the Lut Desert in Iran;
- Saltpans (natural flat expanses of ground covered with salt and other minerals), such as the Chott El Djerid in the Tunisian Sahara.

Finally, wetlands are abundant in some desert areas and, given the generalized arid character of the desert landscapes, they are highly attractive to ecotourism.

Deserts contain biodiversity features that can be highly attractive for ecotourism. These include endemic species exhibiting unique adaptations to aridity that are found in no other biomes (Fig. 2; Weaver, 2001b). Examples of extreme adaptations and uniqueness's found in deserts include:

- Namib Welwitschia (*Welwitschia mirabilis*), among the most ancient organisms in the Plant kingdom and considered a living fossil;

Fig. 1 Examples of landscape features typical of the desert biome with potential for ecotourism. (A and B) Sossusvlei in Namib-Naukluft National Park (Namibia); (C) Es Sba (Mauritania); (D) Guelb el Makhsar (Mauritania); (E) Tassili n'Ajjer (Algeria); (F, G and H) Tadrart (Algeria). Fig. 2 Examples of biodiversity features in the desert biome with potential for ecotourism: (A) African golden wolf (*Canis anthus*); (B) Felou gundi (*Felovia vae*) and Rock agama (*Agama boulengeri*); (C) Desert elephant (*Loxodonta africana*); (D) Namibian giraffe (*Giraffa camelopardalis angolensis*); (E) Greater hoopoe-lark (*Alaemon alaudipes*); (F) Brown-necked Raven (*Corvus ruficollis*); (G) Lanner falcon (*Falco biarmicus*); and (H) Desert monitor (*Varanus griseus*). Courtesy of Frederico Santarém and Jarkko Saarinen.

- Southwestern USA Joshua tree (*Yucca brevifolia*), the symbol of the local National Park that displays a very specialized mutualistic pollination system with the yucca moth (*Megathymus* sp.), which spreads pollen while laying eggs inside the flower in a communal way;
- Fringe-fingered lizards (*Acanthodactylus* spp.) that perform sand-swimming to escape predators in the Sahara Desert;
- Australian thorny devil (*Moloch horridus*) that displays a unique water transportation system through its ridged thorny scales that enable the animal to collect water from simply touching it.

These remarkable adaptations to arid conditions have been used to market them as flagship species, that is, species that due to their morphological, behavioral, and cultural traits can be used as the focus of broader conservation campaigns and can be distinctly promoted according to specific market segment traits. For example, soft ecotourists may prefer large and easily visible species, while hard ecotourists may opt for “last-chance-to-see” endemic endangered species (Lemelin et al., 2012; Santarém et al., 2019). Deserts contain also some of the most endangered species in the world, which may prompt ecotourists to pay high fees to see them in the wild and, thus, contribute financially to their preservation. In addition, wetlands in deserts constitute local biodiversity hotspots supporting particular fauna suitable for ecotourism purposes. For example, the rock-pools of Mauritanian Sahara gather relict populations of West African crocodiles (*Crocodylus suchus*; Brito et al., 2014) and the wetlands near the archeological city of Palmyra (Syria) support a relict colony of the critically endangered Northern Bald Ibis (*Geronticus eremita*; Serra, 2007), thus offering a great opportunity for desert wildlife viewing.

Deserts contain conservation features that improve the chances of wildlife encounters, which enrich the recreational experience for ecotourists. Unique biodiversity is generally safeguarded by a network of protected areas. For instance, the Aïr and Ténéré Addax Sanctuary and the Termit-Tintoumma Natural and Cultural Reserve in Niger were designated to protect the critically endangered and flagship species Addax (*Addax nasomaculatus*), and the Joshua Tree National Park (United States) was established for protecting the native Joshua trees (UNEP, 2006b). Protection of biodiversity and ecological processes is strongest in North American and Australian deserts, where the Grand Canyon (1919) and Simpson Desert (1967) National Parks were established a relatively long time ago. On the contrary, the desert areas of developing countries are still under protected (Brító et al., 2016; Weaver, 2001b). Multiple protected natural sites displaying outstanding evolutionary and landscape features have been recognized even in the most remote parts of deserts, which appeal to a specialized segment of ecotourists that are able to travel long distances to observe unique desert features (hard-desert ecotourists; Santarém et al., 2018).

Human features

Numerous features associated with the historical human occupation of deserts make them attractive to ecotourism (Fig. 3). These include rock art found in caves, mostly depicted as paintings and engravings, illustrating past livelihoods and even past climatic shifts. The World Heritage site of Tassili n'Ajjer in Algeria and the Messak Settafet in Libya are considered open books of History, with thousands of rock paintings and engravings catalogued. Rock art is highly recognizable among international ecotourists because in deserts it is easy to find it in large concentrations, offering abundant possibilities to interpret how humans interacted with the environment and how they developed associated spiritual and community values, making rock art in the desert biome among the best sources of human history.

The low disturbance of desert soils preserved remarkable archeological remains and help to understand how past societies lived in arid environments. Ruins, tombs and other sites of historical land occupation highlight how successive human societies shaped the desert environment (UNEP, 2006a; Serra, 2007). For example:

- The earliest run-off irrigation system supporting large cultivated fields in the world was discovered in the Negev Desert (Israel);
- The ancient city of Palmyra in Syria—where for centuries nomadic Bedouins traded livestock and relative products—has been revealing artifacts of world recognized value;
- Tombs in Egypt show how people worshiped iconic desert species such as the crocodile, represented in art linked to Sobek, god of Nile.

The historical crossing of deserts along trading routes allowed the establishment of trading villages, acting as commercial warehouses and resting places. For instance, the old salt caravans in the Sahara or the Silk Road in Central Asia crossed desert areas through established routes with stopovers in caravan villages. Some of these villages are now classified as World Heritage Sites and offer extensive opportunities to explore desert history (UNESCO, 2018), such as Tombouctou (Mali) and Chinguetti (Mauritania) where extensive trading network enabled the establishment of ancient libraries of notable historical importance.

Deserts display several cultural features associated with human presence that add value to the general recreational experience of the ecotourist and enhance strong connections between dissimilar societies (Fig. 4). Firstly, desert people domesticated camels and dromedaries due to their adapted physiology to withstand hyper-arid conditions and to transport goods along extensive trade routes. Also, humans have long adapted to the harsh environment by using desert elements to counter the high temperatures, strong winds and lack of water (Saarinen, 2016). For instance:

- Tuareg tribes in the Central Sahara use dried bulrush (*Typha elephantina*) to build the roofs of their houses (locally called *Zeribas*) and transport water and milk in reservoirs made of goat skin (called *Guerba*) that keep the water fresh;
- Moors in the West Sahara use dromedary fur and local trees to build their tents (called *khaimas*);

Fig. 3 Examples of historical features associated with human occupation of the desert biome with potential for ecotourism: (A) rock-art representation of giraffe (Tadrart; Algeria); (B) rock-art representation of crocodile (Messak Settafet; Libya); (C) World Heritage Site of Ghadames oasis (Libya), (D) Oualata and (E) Tichit (Mauritania), ancient stop-points for caravans crossing the Sahara; (F) historical library in Chinguetti (Mauritania). Courtesy of José Carlos Brito.

- OvaHimba people (considered the last nomadic people of Namibia) cover their bodies with a self-prepared cosmetic mixture containing an ochre pigment that protects them from the extreme dryness and gives their skin a red characteristic;
- Wool hand-made crafts are manufactured in Egypt for millennia and are now highly appreciated by foreigners looking for desert handicrafts.

Secondly, due to the unpredictability of rain in deserts, humans shaped the environment to benefit their livelihoods and prosper in less favorable climatic times. The best examples of these modifications in the arid environment are the oasis, fertile green areas created for agriculture (mostly date palms, *Phoenix dactylifera*) and whose location has been of critical importance for trading and transportation routes because of the provided shade in the hyper-arid landscape. Oases become fertile when freshwater is extracted on the land surface or underground using man-made structures. Examples include:

- The extensive rock-walled terraces built by the Trincheras people of northern Sonora desert (United States) (surface extraction);
- The *qanats*, networks of subterranean channels developed by the Persian in Iran and now used throughout the North African and Asian deserts (underground extraction).

Fig. 4 Examples of cultural features associated with human occupation of the desert biome with potential for ecotourism: (A) settlement and food-storage systems of OvaHimba people in Opuwo (Namibia); (B) settlement in Ounianga Serir (Chad); (C) oasis (Ziz valley, Morocco); (D) riverbank village (Tassili n'Ajjer, Algeria); (E) desert village (Agadez, Niger); (F) trading route (Air mountains, Niger); (G) Watering livestock from rock-pool; and (H) excavated well from dry riverbed (Tagant, Mauritania). Courtesy of José Carlos Brito and Jarkko Saarinen.

In the region of Gourara and Touat in the Algerian Sahara, about 500 of these systems are still working. Where water-bodies are far from the oases, as in much of the Sahara, the water is lifted to the surface by cantilevered bucket systems (called *shadufs*). Oases vary in extension, but one of the largest and most spectacular is in Uzbekistan, which supports 230,000 ha of irrigated land.

Thirdly, early hunter-gatherers developed uses for local plants and animals to enrich their medicine and diets. For instance, the Topnaar people of the Namib Desert have known uses for 81 plant species and the San people of the Kalahari Desert list more than 100 species of food plants and 55 animal species, some of them with medical uses.

There are unique ethnic costumes and ceremonies that can only be appreciated in deserts. For example:

- Religious ceremonies are pursued by the Shoshone people around the Yucca Mountain (United States) and by the aboriginal people around Uluru (Australia);
- Assyrians, indigenous to Western Asia, are well known by the *khigga*, a folk dance that is traditionally performed during wedding ceremonies.

All modern people living in deserts represent a great repository of knowledge concerning the life in harsh environments, which must be protected and acknowledged by specialized ecotourists seeking to deep their knowledge on local desert cultures (UNEP, 2006a,b; Weaver, 2001a).

Constraints to Ecotourism Development

Desert environments involve certain features that may constraint the development potential of ecotourism. Some may affect particular deserts, such as armed conflicts or poor development conditions limiting accessibility. Others limiting issues may refer to common trends across world deserts, such as increased accessibility and exploitation of natural resources. In all cases, these constraints diminish some of the most valuable desert assets to ecotourists (Santarém and Paiva, 2015; Brito et al., 2016). However, hard and soft ecotourists may perceive these constraints differently and may be prompting to travel or not, respectively, to desert regions where these constraints critically shape desert ecotourism attractiveness (Santarém et al., 2018). For instance, hard ecotourists may support the idea of traveling to remote desert regions of poor accessibility, lacking the comforts provided by regular infrastructures, while soft ecotourism may benefit from the same transportation system created by mining or other extractive industry development purposes (Weaver, 2001a).

Security conditions

Poor security conditions diminish the attractiveness of some deserts to ecotourists, who may feel insecure to travel to regions facing on-going, and, in some cases, long-term conflicts. For example, warfare in North Africa, the Middle East, and in Southwestern Asia has caused environmental destruction (e.g., first Gulf War) and the massacre of local people, migrants and travelers (e.g., Darfur conflict). Conflicts in the Sahara-Sahel are contributing to the extirpation of threatened populations of flagship desert species at the fastest rate ever (Brito et al., 2018). Additionally, conflicts threaten cultural sites of global recognizable importance, such as the historical libraries in Tombouctou (Mali) or the archeological city of Palmyra (Syria). The depletion of natural and cultural values threatens the long-term sustainability of local ecosystems to support any form of tourism (Serra, 2007). Furthermore, the attacks against civilians and, specifically, the kidnapping for hostage taking counteracts against the countries where attacks are perpetrated. For instance, the Ministries of Foreign Affairs of developed countries generally issue advises against traveling to such countries (or define “no-go areas” within countries) as response to protect their national travelers. Another negative aspect of hostage taking for future ecotourism development is the long-lasting reputation of danger associated to the region and the psychological burden imposed by traveling in those regions (even after conditions ameliorate).

Under-developed conditions

Large portions of the world deserts span countries with poorly developed conditions (UNEP, 2006b). In general, desert regions in North and South America, in Australia, and in Southern African countries are perceived as socioeconomically developed and have relatively good infrastructure, whereas deserts in North Africa, the Middle East, and Southwestern Asia display poorer social conditions and infrastructures. Underdeveloped airports, hazardous roads, lack of regular transportation networks, alongside the lack of supporting infrastructures (e.g., hospitals, accommodation, restaurants) may affect the attractiveness of deserts for ecotourists. For example, central Saharan countries, such as Niger and Chad, are considered among the least infrastructure-developed countries in the world, whereas Namibia is recognized to be among the top countries in developed tourism infrastructures, specifically in the desert biome. Although deserts experience less disease outbreaks in comparison to other world biomes, ecotourists may get severely ill from local epidemics, such as the Arizona (United States) endemics Hantavirus Infection, the Rocky Mountain Spotted Fever, and the Coccidioidomycosis Valley Fever (AZDO, 2019).

Political conditions

Ecotourists may express prejudice against visiting deserts located in countries with poor levels of democratic functioning or under sanctions by the international community. The political agendas of several countries in the Sahara-Sahel, Arabian Peninsula and Southwestern Asian deserts are not always aligned with the interests of both local and international communities. In countries ruled by dictatorial regimes, where freedom of thought and speech are often suppressed, animosity between locals and ecotourists may

generate, which negatively affects the promotion of desert ecotourism and the attractiveness of particular regions (Brito et al., 2014, 2016). Furthermore, the high levels of bureaucracy and corruption that usually characterizes dictatorial regimes hamper the establishment of successful ecotourism businesses.

Increasing accessibility

Accessibility plays a critical role in attracting soft and hard ecotourists to deserts but the assessment of its suitability to attract both groups remains poorly studied. On the one hand, increasing accessibility promotes the visit of soft ecotourists, but on the other hand it will tend to deter the hard ecotourists (Santarém et al., 2018). In addition, human population is growing worldwide, and desert areas are no exception; urbanization is increasing, and nomads are becoming sedentary in many world deserts (UNEP, 2006b). These developments cause generalized landscape degradation, with cascading negative effects upon large-sized animals needing vast wild areas during seasonal migratory movements. For example, migratory populations of the flagship African savannah elephant (*Loxodonta africana*) in Mali have been particularly affected by increasing human sedentary in elephant's migratory pathways (Brito et al., 2018). Land degradation and biodiversity loss lessen ecotourists expenditures as desert natural features disappear.

Exploitation of natural resources

The exploitation of natural resources in world deserts, including oil and gas pumping and minerals extraction is expanding. Besides deteriorating habitats in which ecotourism operations are based, they also affect the ecotourists' experience (Weaver, 2001a). For example, oil exploration activities have increasingly affected populations of the critically endangered Addax in Niger. This flagship species has been experiencing dramatic declines since oil exploitation activities started (Brito et al., 2018), which prevent ecotourists from traveling there, as the most important ecotourism asset may be completely depleted from the ecosystem.

Impacts of Ecotourism on Different Desert Facets

Resolutions adopted by the General Assembly of the United Nations highlighted the positive impacts of ecotourism to eradicate poverty and to protect the environment (UNWTO, 2018). Ecotourism has a potential to contribute to these aims in desert environments (Table 2) but it is important to realize that this "potential" can be positive or negative and direct or indirect. Positive impacts tend to occur at broad scales, whereas negative impacts are more localized. Developing desert ecotourism should also consider these aspects to maximize return-on-investment scenarios at multiple scales (from the business owner to local communities passing through state governments) and to diminish economic inefficiencies in peripheral regions, while preserving local environments at the same time. Despite these potential negative impacts, ecotourism has been suggested to be among the best tools to address economic and social imbalances in deserts (Santarém and Paiva, 2015).

Table 2 Potentially positive and negative impacts from ecotourism in the desert biome

Positive	Negative
● Protects species and habitats ● Repairs degraded habitats ● Funds protected areas ● Maintains ecosystem services ● Subsidizes scientific research ● Raises conservation awareness and fosters environmental-friendly behaviors ● Generates direct/indirect employment and revenues ● Multiplies systems of generating revenues ● Funds community-based projects ● Stimulates other forms of tourism ● Supports pharmaceutical investigation ● Improves education ● Diminishes gender inequalities ● Sustains ancient practices ● Provides spiritual benefits ● Fosters social inclusiveness	<i>Environmental impacts</i> ● Disturbs or destroys wildlife ● Potentiates species invasiveness ● Restructures habitats permanently ● Generates local pollution and waste ● Boosts water abstraction ● Diverts funds from less to more charismatic species <i>Economic impacts</i> ● Needs substantial initial investments and operational costs linked to remoteness and climate ● Sensitivity to long-term uncertainties in generating revenues ● Increases medical assistance costs ● Disrupts local subsistence ● Creates income inequalities and increases economic pressures <i>Sociocultural impacts</i> ● Increases cultural shocks ● Erodes local power ● Generates animosity/resentment

Modified from Weaver, D. B. (2001). Ecotourism. Queensland, Australia: John Wiley & Sons Australia, Ltd.

Ecological Impacts

Positive

Ecotourism may protect desert biodiversity through financial mechanisms that support breeding, feeding, translocation, antipoaching, and other conservation programs with direct positive effects on species population growth and viability (Buckley et al., 2016). For instance, the populations of cheetah (*Acinonyx jubatus*) in the Kgalagadi Transfrontier Park (South Africa) and of the Western Barred Bandicoot (*Perameles bougainville*) in the Arid Recovery Reserve (Australia) rely on tourism revenues for their conservation. Ecotourism may also benefit biodiversity and human populations when it contributes to the restoration of degraded habitats and environments that help to maintain and safeguard ecosystem services (Buckley et al., 2016; Weaver, 2001a). These include provision of clean water, which in deserts is a scarce and highly valuable asset, and raw materials, such as palm trees for timber production, and medical resources, such as venoms from desert vipers for antivenom development (Weaver, 2001a). Ecotourism may fund the establishment of new protected areas in desert countries and maintain and increase old ones. For instance, 12% of the Namibian protected areas' budgets are assured by tourism expenditures (Buckley et al., 2012).

Ecotourism may also subsidize scientific research on species and protected areas (Wearing, 2001), by making people donating more funds to environmental causes and creating "environmental watchdogs" (nature activists that will intervene in favor of the environment; Weaver, 2001a). For example, the conservation of the northernmost population of the African savannah elephant in the Gourma region (Mali) is enforced by a community-based vigilance network composed by 520 "eco-guardians" living throughout the elephant range, which continually patrol and alert about elephant locations, numbers and behavior, elephant deaths, and poaching incidents (Brito et al., 2018). By raising conservation awareness and fostering environmental-friendly attitudes among local communities, policy makers and the likes, ecotourism may influence communities' nature-pro behaviors, improving the sustainable harvesting of food and natural resources (Lindberg, 2001; Wearing, 2001; Weaver, 2001a).

Negative

Recreational activities in deserts are usually based in all-terrain vehicles, which may degrade the landscape and increase local pollution. The exhaust gases released to the atmosphere may also affect sensitive desert vegetation. For example, many plants of the Mojave Desert (United States) died when exposed to various vehicles' pollutants in a laboratory experiment. The impacts of chemical fuel leakage to the ground and of soil compacting and erosion may take decades to disappear. For instance, the soils of the Joshua Tree National Park (United States) were found to be compacted from 2 to 5 cm because of constant vehicles traffic (Ouren et al., 2007). Motorized driving may also run-over desert fauna or destroy vertebrate ground nests. For example, the populations of desert tortoise (*Gopherus agassizii*) and Couch's spadefoot toad (*Scaphiopus couchii*) have decreased in areas with high off-road vehicles passage in Mojave and Colorado deserts (United States) because vehicles collapsed burrows. In addition, they may produce noise that disturbs local fauna, which ultimately alters animal behavior, reduces preys' capabilities of detecting predators, and stimulates aestivating animals to emerge from their burrows at inappropriate times. For instance, kangaroo rats (*Dipodomys deserti*) in California deserts (United States) experienced hearing loss when exposed to continuous sound produced by dune buggies, which made them unresponsive to predator sounds for weeks (Ouren et al., 2007). Additionally, desert vegetation is under increased risk of vehicles passage, being reported that lichen communities of the coastal Namib desert are eliminated by a single vehicle passage (UNEP, 2006b).

Transportation can contribute to the proliferation of invasive species in deserts, particularly when humans assist plant seeds or invertebrates to travel long distances, for instance attached to vehicles. Proliferation of invasive species may also be facilitated by vehicles' exhausting gases. For example, annual grasses prone to wildfires proliferated after a CO₂ increase in the atmosphere of the Mojave Desert (United States), accelerating local fire frequency in regions where they did not exist before (UNEP, 2006b). Keeping vehicle speeds down and, more importantly, using other forms of transportation, such as camel trekking or air ballooning, can reduce air and soil pollution, preserve the quality of the surrounding environment, and minimize wildlife direct damages (UNEP, 2006a).

Permanent environmental restructuring may occur when setting and operating tourism-supporting infrastructures. Locally, the surrounding landscapes may become less natural, sound and light pollution may become more frequent, and the soils sustaining those infrastructures may become permanently altered. In the long-term, ecotourism may also generate waste and contaminate soils and the scarce water resources available, if wastes and sewage waters are not properly treated (Serra, 2007; UNEP, 2006a). As ecotourism potentiates the development of other economic activities, additional infrastructures may be constructed, which can magnify impacts on soil and water, particularly when less-benign energy sources are used (Weaver, 2001a).

Several measures should be taken to minimize the ecological impacts of ecotourism. For example, construction of infrastructures should opt for local materials to minimize landscape impacts. Alternative energies should be preferred when building/recovering infrastructures, such as wind and solar energy that provide feasible energy production in deserts. Ecotourists should be encouraged to take toxic wastes (like batteries and aerosols) back home and arrangements should be enforced to deal with waste removal. For example, companies from Mauritania and France set-up a joint waste collection protocol in Chinguetti, a highly visited UNESCO World Heritage Site (UNEP, 2006a).

Water abstraction for serving ecotourism activities and accommodation may cause water shortages. This problem is amplified by the natural dryness of deserts. For example, the small dune fields throughout the Taffilat region of Morocco are threatened by the massive and unsustainable construction of tourism facilities, which are progressively surrounding them. Making use of systems that reduce water-levels consumption and recycle sewage waters should be preferred whenever possible. Raising awareness among

ecotourists about the consequences of their actions should stress the scarcity of water resources and the unsustainable nature of its excessive use in desert environments (UNEP, 2006a).

To a lesser extent, the promotion of the most charismatic desert species by ecotourism operators may counteract against other species less appealing to the general public, diverting funds from the latter to the former. This may have a negative impact on less charismatic desert species when international ecotourists restrain from conserving them (Weaver, 2001a). In alternative, the promotion of flagship fleets, that is, groups of species displaying similar appealing traits that raise the profile of more than one species to attract different segments of the society, may maximize conservation marketing and return-on-investment scenarios for ecotourism in deserts (Santarém et al., 2019).

Economic Impacts

Positive

Ecotourism can provide direct and indirect economic benefits to desert communities, offering local employment as tour guides, receptionists, cooks, planners etc. Some jobs are desert-specific and benefit from local people's in-depth knowledge of the environment, such as camel drivers, who become indispensable to convey desert cultural knowledge to ecotourists. Ecotourism may also provide alternative ways of empowering local communities, for instance by creating opportunities for selling desert crafts to travelers (UNEP, 2006a), further benefiting the whole community. Ecotourism may stimulate other forms of tourism, such as cultural tourism or adventure tourism, and act also as a catalyzing agent to generate other jobs that feed it directly or indirectly. By creating employment, ecotourism displays an underlying multiplier effect that benefit local communities and regional and national governments (Wearing, 2001; Weaver, 2001a). For instance, it may help creating jobs in provisioning (such as food production or bed linen) and services sectors (such as water cleaning, infrastructure maintenance or banking and accounting). These indirect effects occur, for instance, when local restaurants use ecotourists' expenditures to purchase local goods and services from other businesses, and to pay employees that will spend their wages in buying external goods and services. This generates a circular economy where all parts benefit. Additionally, all these sectors must pay taxes, fees, and licenses that generate increased stimulus to fiscal policies (Lindberg, 2001). Peripheral and marginalized regions of some world deserts should be the ones to benefit the most, which labels ecotourism as a sustainable tool to eradicate extreme poverty (Lindberg, 2001; UNWTO, 2018; Weaver, 2001a). For instance, local people generated multiple jobs (directly and indirectly related to the tourism sector) after successive Communal Conservancies were created in Namibia.

Residents of ecotourism destinations may benefit from revenue-sharing programs that fund community-based projects, such as sustainable agriculture or clinic and school construction and upgrade. For example, ecotourism helped the Torra Conservancy of Wilderness Safaris' Damaraland Camp in Namibia to release c.\$120,000 of the profits to upgrade local schools in 2002 (Butler et al., 2009). Ecotourism may also increase the investigation and procurement of desert natural assets for food production, such as palm dates, or pharmaceutical developments, such as desert snake venoms, which benefit both local and global communities (Weaver, 2001a).

Negative

Initial investments on land acquisition, materials' purchases (including vehicles), initial staff training, and promotion have substantial costs, but on-going operational costs, such as wages, infrastructures and vehicles maintenance (meaningful in deserts due to the remoteness and harsh climate of the biome—temperature, sand and salt winds), and continuous marketing bail out most of the operational costs when developing desert ecotourism (Serra, 2007). Ironically, these costs translate into benefits when considered from the perspective of the people that benefit from them (Weaver, 2001a). Building infrastructures nearer established cities, villages and oases, and opting for vehicles with anticorrosive materials may diminish the depreciation speed of these goods.

Ecotourism development in the desert biome may be sensitive to long-term uncertainties in generating revenues. These may arrive from the general supply-and-demand risks but also from specific traits of some deserts, such as regional insecurity, or diseases outbreaks. These aspects may make initial investments unreliable, resulting in no-profit situations or, even worse, in substantial economic losses (Brito et al., 2014, 2016; Weaver, 2001a). Ceasing regional conflicts and developing control measures to prevent disease outbreaks helps to reestablish operations. For instance, after a 10-year break period following the growing in regional insecurity, only recently international tourist agencies are again offering services to visit some Sahara-Sahel countries. That is the case of Mauritania, where French carriers reestablished flights to well-known touristic places in the Adrar and Ouadane areas.

Ecotourism may incur in indirect economic costs when wildlife encounter accidents occur, particularly when flagship species protected for ecotourism become cause of human injuries. For example, the venomous desert snakes American horned rattlesnake (*Crotalus cerastes*) and the North African horned viper (*Cerastes cerastes*) are among the world's most toxic and they may bite visiting ecotourists, generating additional costs related to medical assistance, notwithstanding the animosity that injured people create towards typical desert flagship species (Weaver, 2001a). Developing clinics and hospitals in strategic places would allow injurers to be healed faster and properly, reducing the costs of transportation of diseased people. Multinational pharmaceuticals can also target efforts to develop strong antidotes specific to each of the several desert venom species, which entail substantial costs in research and development but translate into profits for the world society at many scales in the long term.

Especially in the Global South, ecotourism operations are often owned and monopolized by international business and foreign actors controlling all processes from the land acquisition to the establishment of an ecotourism company, including the provision of related services. Considerable negative impacts might arise if foreign control and importation of external products leak all the

revenues away from the local community and the regional states where ecotourism takes place (Lindberg, 2001; Weaver, 2001a). Including local communities in early strategic ecotourism development plans and developing strong policies against monopolies and expropriation of local deserts from foreigners enforces local people rights and grants that most of the revenues stay with who need them the most. Corporate social responsibility is a recent type of business self-regulation that can help on this issue, as it includes men, women and the youth in strategic plans to increase long-term companies' profits.

Ecotourism, as any other form of tourism, may sometimes exacerbate income inequalities within community members (Lindberg, 2001). Ecotourism may counteract against local interests and preferences by increasing demand-to-supply and the prices of house rents, local goods and services, which create economic pressures that may disrupt people financial stability and obliges them to leave the region, and may extirpate local ancient cultures (Lindberg, 2001; Wearing, 2001; Weaver, 2001a). In Mmatshumo village of the Makgadikgadi pans landscape (Botswana), for example, some communities have become involved in ecotourism, which has resulted in a decline or even termination in traditional livelihood activities like subsistence hunting and gathering. However, not all community members have been able or willing to work with ecotourism and related employment, which has caused increasing inequalities in communities (Lenao et al., 2014). To avoid ecotourism related local inequalities, strong national policies promoting equitable access to resources and considering the needs of local people may boost the development of desert communities. Additionally, alternative jobs should be considered in remote regions where few desert attractions for ecotourism exist, thus allowing people to sustain the same lifestyle as those living in ecotourism-rich regions. Regional agreements and international conventions must develop strong legal frameworks for the protection of desert natural assets and the interests of indigenous people.

Sociocultural Impacts

Positive

Successful ecotourism development can diminish gender inequalities and give power to women and youth embracing qualified jobs. It has the potential to improve education in peripheral and marginalized desert regions and to generate resources for community-based development projects, improving people's acceptance of alternative ways to generate income while preserving desert resources (UNWTO, 2018). For instance, nomadic Bedouins that once hunted birds in Palmyra (Syria) adopted more sustainable activities by becoming ecoguides (Serra, 2007). Ecotourism creates markets for local products, thereby sustaining and promoting ancient practices, and making local people proud of their traditions. By turning local knowledge, cultural skills and traditional craft skills into attractions to travelers, ecotourism may help to preserve the desert cultural heritage. For example, the Ksour Route is a project developed to show ecotourists the old trade routes across the Southern Algerian Sahara and that aims to rehabilitate traditional architectural heritage. A spectacular example comes from the La Ruta de Sonora Ecotourism Association, which is a transboundary commitment between United States and Mexico to protect the natural and cultural heritage of the Sonora desert through desert trans-frontier ecotourism (UNEP, 2006a). Ecotourists that spend more time understanding host communities' habits and patterns will likely respect local knowledge and traditions and promote them in their own countries, creating a society ruled by respectful understanding of social differences (Wearing, 2001).

Ecotourism may provide many spiritual benefits to the individual, maximizing nature enjoyment for locals and ecotourists alike (Weaver, 2001a). Deserts are particularly prone to this spiritual relief sensation, given their extensive landscapes that offer a perception of solitude and deepens root-connections with nature. Ecotourism may also potentiate social inclusiveness by accommodating a wide spectrum of the society, particularly individuals with substantial physical and mental limitations that could find barriers to their enjoyment in other types of activities (UNWTO, 2018; Weaver, 2001a). Deserts are especially suitable to accommodate disabled people, as their extensive plains and sparse vegetation may facilitate locomotion.

Negative

While having a great potential to benefit communities, ecotourism operations can generate cultural conflicts and shocks between ecotourists and indigenous communities when certain aspects of local lifestyle are in opposition with principles defended by ecotourists (e.g., brutal killing of a charismatic animal for ecotourists that is at the same time a valuable food for local people; Weaver, 2001a). To prevent conflicts and cultural shocks, thematic travel arrangements should respect desert traditions and be made only after consulting desert local communities (UNEP, 2006a). Marketing ecotourism should make aware the local traditions and potential conflicts of interest to visitors when visiting particular desert regions.

Ecotourism may transform and erode local power systems and structures when new business-oriented local or nonlocal elites take control over local assets. Businesses that impose control over local desert assets, like food and water, may create resentment among local people. Also, disruption of established social relationships may potentiate local resentment upon nature that is protected for ecotourism, particularly when local access to natural assets is blocked due to stringent nature protection laws but allowed to ecotourists visiting the region. Deliberate acts against nature (e.g., intentional wild killing and habitat destruction) may occur to intentionally shock the visitors (Lindberg, 2001; Serra, 2007; Wearing, 2001). Fortunately, there are few or no reported records of these behaviors in deserts to date. Ecotourism may be seen as a complementary tool to other local practiced land-uses, and not a mean to the obstruction of ancient practices. Therefore, access to local resources should not be exclusively granted to foreigners or passively prohibited to locals.

Ecotourism may generate resentment among people from the same community, when some or all of them are not involved in the ecotourism planning process, or when locals feel their visions and traditions are being neglected. Even worse, foreign-owners of

Fig. 5 An example of successful cooperation between local communities, research institutions, national park staff and governmental institutions in the promotion of environmental responsible acts in deserts and in early adoption of ecotourism as a means to preserve the West-African crocodile (*Crocodylus suchus*) in Diawling National Park, Mauritania. Courtesy of José Carlos Brito.

ecotourism businesses may impose alien values (e.g., globalism and Western modernization) that can erode local ones and may lead to sociocultural tensions. The involvement of local communities is one of the most critical components in determining the success of local support for nature conservation and desert ecotourism development (Fig. 5; Serra, 2007; Wearing, 2001). Inclusive local participation in ecotourism development through corporate social responsibility initiatives can help to establish scenarios that benefit all ecotourism stakeholders without jeopardizing local values (UNWTO, 2018). To achieve the best standards of social fairness and equity it is required to consider the inherent specificities of each desert community when developing ecotourism. An example of good practice in action came from Uluru Kata Tjuta National Park (Australia), where desert Aboriginal people operated a tour company and managed all the activities, including the interpretation of Aboriginal rock-art, medical plants, and bush cookery (UNEP, 2006a).

Conclusions

The desert biome contains a wide spectrum of potentials and constrains for ecotourism planning, development and management. On the other hand, ecotourism may deliver different levels and extents of environmental, economic and sociocultural impacts across global deserts. To have successful ecotourism operations, the diversity of potential impacts needs to be understood and proactively considered. Particularly because they may contribute to the increase or the depletion of desert natural and cultural features appreciated by ecotourists. We suggest that the various impacts of ecotourism are managed in respects with the specificities of each desert context, considering its people, wildlife and ecosystems. In the desert biome, ecotourism should be developed in ways that are based on effective management tools and responsible practices leading to sustainable governance and use of the natural and cultural heritage resources of deserts. Additional research efforts are highly needed in this regard, particularly in what refers the studying of alternative and sustainable development methods. Although ecotourism is not a panacea for widespread biodiversity losses, if properly managed, it can relief some of the threats to desert biomes. Ultimately, desert ecotourism can act as a sustainable tool to achieve the Sustainable Development Goals of the United Nations, contributing positively to the wellbeing of people living within deserts and to threatened desert heritage.

Abstract

Life near the poles is tough but vulnerable. The very adaptations that allow both marine and terrestrial life to survive the bitterly cold winters and short, cool summers can become liabilities in a rapidly warming world. Ecological patterns and long-term species associations are already starting to break down in some Arctic regions. Thus far, the marine biota of Antarctic waters has not experienced such high rates of environmental change, but incursions of warm water caused by changes in wind patterns and ocean circulation will wreak havoc if they melt the sea ice and cause changes in krill distribution patterns.

Introduction

The two polar regions of planet Earth are very different except for two common denominators: bitter cold and division of the year into a long season of darkness (winter), followed by a long season of constant sunlight (summer). The extreme cold of polar winters is quite remarkable, given the more-or-less temperate climate of much of the planet. The average yearly temperature of the planet is 15 °C. The average winter temperature at the North Pole is –40 °C, and at the South Pole it is –60 °C. The South Pole is so much colder than the North Pole because the South Pole sits near the middle of an ice-bound continent, Antarctica. The South Pole sits atop a featureless, barren, windswept ice sheet at an elevation of 2835 m above sea level (Fig. 1). This pole is located about 1300 km inland from the nearest sea, so there is no moderating effect of oceanic climate here. In contrast, the North Pole sits atop the Arctic Ocean. Although this location is covered year-round by sea ice, it sits at sea level and regional temperatures are moderated somewhat by the proximity to ocean waters. This difference between the poles is brought out by their average summer temperatures. The North Pole averages 0 °C in summer, while the South Pole averages –28 °C. Antarctic climates are reviewed by Gonzalez and Vasallo. Climates of High Arctic regions are reviewed by Davy. Climates of Arctic tundra regions are reviewed by Serreze. Greenland climates are reviewed by Westergaard-Nielsen et al.

Life in Antarctica

Antarctic terrestrial biomes are reviewed by Parnikoza and Kozeretska. Not surprisingly, there is essentially no life on the Antarctic ice sheets and only small patches of life along the ice-free margins of the Antarctic ice sheets. In fact, less than 1% of the surface of Antarctica is free of ice. The diversity of life in these small patches of the continent is extremely small. Only two species of flowering plants are found here: Antarctic hair grass (*Deschampsia antarctica*) (Fig. 2, upper right) and Antarctic pearlwort (*Colobanthus quitensis*) (Fig. 2, upper left) (British Antarctic Survey, 2019a). These occur on the South Orkney Islands, the South Shetland Islands and along the western Antarctic Peninsula. The dominant plants of Antarctica are the cryptogams, including 100 species of mosses (Fig. 2, center left), 25 species of liverworts, 300–400 species of lichens (Fig. 2, center right) and more than 20 species of macro-fungi. The greatest abundance and diversity of these primitive plants occur on the western side of the Antarctic Peninsula where the climate is generally warmer and wetter than elsewhere in the Antarctic continent. But there is also plant life in the very dry, cold, ice-free regions known as the dry valleys of Victoria Land. Here there are algae, fungi, and lichens that live in cracks and pore spaces inside the sandstone and granite rocks. These endolithic organisms live just inside the surface of rocks—sheltered from the desiccating, freezing winds, but close enough to the surface to collect enough sunlight to carry out photosynthesis.

Terrestrial animals of the maritime regions of Antarctica include arthropods (primarily springtails and mites), earthworms and mollusks (British Antarctic Survey, 2019b). Higher insects include spiders, beetles, and flies, but there are only found in the areas with the least severe climate, such as the sub-Antarctic islands. A small number of micro-invertebrate species are also present. These

include nematodes, tardigrades, and rotifers. The population densities of these tiny organisms are often high. The interior regions of the continent are almost devoid of invertebrates. No higher insects are present, and micro-arthropods are restricted to the limited patches of vegetation. Nematodes are the dominant group here. From one to three different nematode species are known to inhabit the cold deserts, one of which is a predator on the others. These cold desert soils represent the least diverse habitats on Earth.

Plankton

The greatest abundance and diversity of life in the South Polar region is found in the Southern Ocean. Because the seawater here is very cold, it holds high concentrations of oxygen, facilitating the biological productivity of these waters. Like all ecosystems, the Antarctic marine system begins at the bottom of the food chain, with plankton. The plankton of open Antarctic seas is reviewed by Smith and Meyer. The phytoplankton of Antarctic waters are dominated by diatoms, with nanophytoplankton, haptophytes, and dinoflagellates important locally. Antarctic krill (*Euphausia superba*) are an important macrozooplankton. Krill are small crustaceans that grow up to about 6 cm in length. These are among the largest species of the Antarctic plankton. Krill are the most important organisms in the diet of many predators, including fish, squid, penguins, whales, and seals. Hunting for krill is facilitated by their habit of living in dense swarms of 10,000 or more individuals per cubic meter of water. Copepods are also an important component of the Antarctic zooplankton. They feed on phytoplankton and in turn, are eaten by krill and fish.

Marine Mammals

The ecology, behavior, and distribution of Antarctic marine mammals are reviewed by Bester. Whales were almost wiped out in the Southern Ocean by whalers in the 19th and 20th centuries, but their numbers have rebounded in recent years ([British Antarctic Survey, 2019c](#)). The whales of the Southern Ocean head to warmer waters during the Antarctic winter. Calves are born in these warmer seas, as the Southern Ocean is simply too cold for them during the first few months of life. The whales return to the Southern Ocean in austral spring, following the receding margins of sea ice. These boundary waters between sea ice and open ocean are areas of high biological productivity that provide rich feeding grounds.

Two groups of whales are found in the Southern Ocean near Antarctica: the toothed whales and the baleen whales. The toothed whales prey on fish, squid, penguins, sea-birds, seals and sea lions, using echolocation to find their prey. Toothed whales include the sperm whale (*Physeter macrocephalus*) ([Fig. 3](#), upper left), more than 20 species of beaked whales, and the killer whale (*Orcinus orca*) ([Fig. 3](#), upper right), which is actually not a whale, but is the largest of the dolphin species. The killer whale population of the Southern Ocean now numbers over 160,000 individuals. The other dolphin species found in the Southern Ocean is the hourglass dolphin (*Lagenorhynchus cruciger*) ([Fig. 3](#), center left).

Baleen whales have fibrous plates of baleen instead of teeth, which they use to strain plankton and small fish from seawater ([Fig. 3](#)). The baleen whales of the Southern Ocean include the blue whale (*Balaenoptera musculus*), the fin whale ([Fig. 3](#), center-right) and the humpback (*Megaptera novaeangliae*). The most numerous baleen whale is the Minke whale (*Balaenoptera acutorostrata*), a species that spends much of its time in the Antarctic near the edge of the sea ice.

Seals are divided into two groups: true seals and eared seals, the latter comprising fur seals and sea-lions. The numbers of individuals can be quite high. For instance, there are 65,000 breeding fur seals on Bird Island. Seals feed on fish, squid, and krill. Thick layers of blubber beneath their skin provide a food reserve as well as insulation. All Antarctic seals also have a layer of fur, giving additional insulation when they are hauled out on land or ice. Seals leave the water to breed, rest and molt. There are six Antarctic seal species. Four of these are ice-habitat specialists. They breed on sea ice in spring. These include the leopard seal (*Hydrurga leptonyx*) ([Fig. 3](#), lower left), the Ross seal (*Ommatophoca rossii*), the Weddell seal (*Leptonychotes weddellii*) and the crab-eater seal (*Lobodon carcinophagus*) ([Fig. 3](#), lower right). The Antarctic eared seals comprise just two species, the Antarctic fur seal (*Arctocephalus gazella*) and the elephant seal (*Mirounga leonina*) ([Fig. 3](#), bottom). Both species swim north of the pack-ice zone and breed in dense colonies on beaches.

Probably the greatest immediate threat to Antarctic krill-feeders (baleen whales, seals, penguins) is the constriction of seasonal pack ice, combined with a decline in krill biomass in the Southern Ocean. Antarctic krill (*Euphausia superba*) populations have declined by 40–80% in the last three decades around the South Shetland Islands near the tip of the Antarctic Peninsula ([Trivelpiece et al., 2011](#)). Historically, krill have been one of the most abundant macro-zooplankton on Earth, with a combined biomass equal to that of all fishes in the ocean. Their decline in recent decades is due to multiple factors, including reduction of sea ice from regional climate warming and the development of commercial krill fishing to supply omega-3 oil capsules to the health food industry ([Fig. 4](#)). The western Antarctic Peninsula is warming faster than most of the rest of the planet. Winter temperatures have risen about 6 °C over the past 60 years, reducing sea ice cover. Krill use the sea ice both for shelter from predators and to harvest algae growing below the ice.

Krill are a vital food resource for eight species of baleen whales in Antarctica; 17 species of penguins rely on krill for food. The six seal species of Antarctic waters rely either directly or indirectly on krill. The loss of sea ice has a negative effect on krill numbers as well as negative effects on seals, because sea ice loss reduces the availability of suitable breeding and resting habitats for seals, as well as providing protection from predators, such as killer whales. A major issue in Antarctic marine mammal conservation is our lack of knowledge concerning the population sizes of the various species and the infrequency of censuses. As things stand today, only large-scale changes can be detected, so gauging marine mammal responses to gradually developing threats is almost impossible.

Fig. 4 Flow chart illustrating the causes of recent Antarctic krill (*Euphausia superba*) declines (by author) and impacts on penguins and marine mammals that feed on krill. Krill photo courtesy of the Australian Antarctic Division.

One topic in Antarctic ecosystems that was not covered in this section concerns declines in penguin populations. Some dramatic declines have taken place in recent decades. For instance, [Weimerskirch et al. \(2018\)](#) report that the largest king penguin colony in the world, on Ile aux Cochons in sub-Antarctic waters, has declined by 88% over the past 35 years, from more than 500,000 breeding pairs to just 60,000 pairs. The reason for this decline remains unknown, although possible causes include climate change, disease, competition for resources, and an El Niño event in 1997.

Sea-surface temperature (SST) has been found to play a key role in penguin distribution and abundance. [Evans et al. \(2019\)](#) studied population changes in the little penguin (*Eudyptula minor*) during a marine heatwave in 2016 off the coast of Tasmania. During this high SST event, the probability of penguin presence decreased rapidly as the temperature rose above the long-term average SST. Regional SSTs were markedly cooler in 2018, but again the authors found that the probability of penguin presence decreased almost linearly in locations with temperatures above the mean. In fact, these penguins selected a mean SST of 17.8 ± 0.4 and 17.4 ± 0.2 °C in 2016 and 2018 respectively. Similarly, penguins opted for a narrow summer thermal range in other colonies studied. But it is not the water temperature per se that is attracting the penguins. The penguins feed on krill, and the krill live in cooler waters. Hence, there is a link in this region between the cold-adapted krill species and the preference shown by little penguins for cooler water regions. Penguins target krill and perhaps small fish that also feed on krill in cooler water. Thus, the penguins follow the krill. This demonstrates that penguins need water of a certain temperature to feed on their preferred prey. If sea-surface temperatures rise in the Southern Ocean because of global warming, then penguins, krill-feeding marine mammals, and other top-end predators may face food shortages.

Life in the High Arctic

Unlike the Antarctic, where a large continent is situated over the pole, the Arctic region is almost equally divided between land and sea. The land areas include the northern regions of North America and Eurasia, Greenland, and groups of islands that extend north to about 83°N. Both animal and plant life decline in abundance and diversity in the High Arctic, which is essentially polar desert.

Marine Life

As discussed by Lovejoy, the plankton of the Arctic Ocean are taxonomically and functionally diverse, and most species have pan-arctic distributions. The Arctic Ocean and adjacent seas are a combination of highly productive shelf regions and polynyas, and extremely oligotrophic basins north of 70° latitude. The plankton form complex trophic webs that support substantial populations of marine mammals and birds. As with the Antarctic phytoplankton, the lack of light for much of the year in the northern high latitudes, combined with ice cover, constrains annual photosynthetic productivity by the phytoplankton. Both Arctic and Antarctic seas have polynyas: areas of open water surrounded by sea ice that persist throughout the year. Polynyas provide year-round access to light which, combined with the resuspension of nutrients, extends the normally short arctic phytoplankton bloom. This boost in primary productivity helps maintain diverse zooplankton communities.

The cold, nutrient-rich waters of the Arctic, especially the seas on the margins of the Arctic Ocean, support a rich and diverse marine mammal fauna ([Fig. 5](#)). The shelf regions of the Arctic Ocean are the most extensive of all oceans, covering about 50% of its total area.

These shallow waters contribute to the abundance and diversity of Arctic marine life. Arctic marine ecosystems are home to more than 2000 species of algae, and over 5000 animal species, ranging from zooplankton, fish, and seabirds to apex predators such as the polar bear (*Ursus maritimus*) and narwhal (*Monodon monoceros*). The marine mammals of this region are discussed in Elias.

Current threats to Arctic ecosystems are discussed by Gamburg. One widespread problem is the pollution of land and sea by mercury from anthropogenic sources. Mercury levels in the Arctic are now three times higher in freshwater and 10 times higher in marine ecosystems than they were in pre-Industrial times. Over the past 150 years, there has been a 10-fold increase in mercury levels in the upper trophic level marine animals, including beluga, ringed seal, polar bear, and birds of prey. Mercury, like persistent organic pollutants (POPs), accumulates in animal tissues and concentrations increase up the food chain. Populations of some species at the top of the marine food chain, such as the polar bear, pilot whale, narwhal, beluga, and hooded seal are at high or severe risk of mercury poisoning.

Both the lands and seas of the Arctic are rapidly warming in response to steady increases in global Greenhouse Gas (GHG) emissions. Summer sea surface temperatures (SST) in the Arctic Ocean are driven mainly by the amount of incoming solar radiation

absorbed by the sea surface. Greater warming occurs in ice-free regions because the open water reflects little light back into space, whereas sea ice reflects a great deal of solar energy. The open ocean reflects only 6% of the incoming solar radiation and absorbs the rest, while sea ice reflects 50–70% of the incoming energy. August SSTs have warmed significantly since 1982 for most regions of the Arctic Ocean that are ice-free in August. One of the biggest biological impacts of this warming is the loss of sea-ice cover. Sea ice loss represents a huge habitat reduction for sea-ice algae and phytoplankton. This habitat loss has severe consequences for the Arctic marine food chain because these phytoplankton represent 57% of the primary productivity of the Arctic Ocean. Sea-ice also serves as a stable platform from which various marine mammals operate in the winter months, including walrus, seals, and polar bears.

One of the greatest obstacles to our understanding of the ongoing changes in the biodiversity of Arctic marine ecosystems is the fragmented nature of our knowledge and the paucity of consistent and regular long-term monitoring programs (Michel et al., 2013). Anthropogenic changes are happening at unprecedented rates. These range from GHG warming to the opening up of new shipping routes, the increasingly northward development of fishing grounds, and the drilling of oil and gas wells on the continental shelves. The effects of these stressors on Arctic marine ecosystems remain poorly understood, and the impact of cumulative effects make predictions of biotic responses extremely difficult. Shifts in ecosystem structure, species interactions, and trophic pathways need to be understood in the context of both short- and long-term trends, to develop management strategies to maintain the diversity and sustainability of Arctic marine ecosystems.

Terrestrial Vegetation

The vegetation zones of the Arctic are divided into three groups: the sub-arctic, the low arctic, and the high arctic (Fig. 6). The sub-arctic regions extend to regions south of 60°N in both Eurasia and North America. This vegetation is dominated by coniferous trees.

Fig. 6 Map of the Arctic, showing the principal vegetation zones (High Arctic, Low Arctic, Sub-Arctic) (by author).

Fig. 7 Dwarf shrub tundra near Kotzebue, Alaska (photo by author).

Few broadleaved trees can survive the very low winter temperatures. This type of forest is known as boreal forest in North America and is also known as taiga in Eurasia. Plant diversity is low in the sub-arctic, but the boreal forest is the largest forest biome on Earth. Most boreal forests are in northern Russia and Canada.

The low arctic zone occupies the northern edges of the two continents, the southern half of the coastal regions of Greenland, Baffin Island, and Victoria Island in Canada. The general term for the vegetation of this region is tundra. The word tundra originates from the Finnish word *Tunturi*, which means “completely treeless heights.” The number of vascular plants in low arctic tundra ranges from fewer than 50 species near the northern boundary of the biome to as many as 500 species at the southern boundary, near treeline. Altogether, the low arctic regions of the world are home to about 1700 plant species. The vegetation in most low arctic landscapes is dominated by dwarf shrubs, heaths, mosses and lichens (Fig. 7). In North America, the dwarf shrubs include dwarf birch (*Betula nana*) (Fig. 8, upper left), Arctic willow (*Salix arctica*) (Fig. 8, upper right), Labrador tea (*Rhododendron tomentosum*) (Fig. 8, middle right), crowberry (*Empetrum* sp.) (Fig. 8, lower left), Lingonberry (*Vaccinium vitis-idaea*) (Fig. 8, bottom right), and white dryas (*Dryas octopetala*) (Fig. 8, lower right). Herb and lichen species are also very common, in mixture with other vegetation. One important lichen species is reindeer lichen (*Cladonia rangiferina*) (Fig. 8, lower left), which forms an important part of the diet of caribou, moose and muskox in North America and for reindeer in Eurasia. Wetlands are very common in lowlands throughout the North American tundra. The height of woody plants in the North American arctic depends mainly on the summer temperature regime. At the northern end of the low arctic tundra, where average July temperatures range from 3 to 5 °C, there are only prostrate dwarf shrubs. Further south, where average July temperatures range from 5 to 7 °C, the shrubby vegetation increases in height up to 15 cm. Close to the southern boundary of low arctic tundra, erect dwarf shrubs grow up to 40 cm tall. Here the average July temperatures are 7–9 °C. At the treeline, mean July temperatures are between 10 and 12 °C, and woody shrubs grow up to 2 m tall.

The Arctic tundra of the Eurasian mainland is similar in appearance to that of North America, but some different plant species are dominant. These include cotton grass (*Eriophorum* sp.) (Fig. 8, middle left), sedges (*Carex* sp.), a different species of dryad (*Dryas punctata*), in addition to dwarf shrub willows, crowberry (*Empetrum* sp.) (Fig. 8, bottom left), lingonberry (*Vaccinium vitis-idaea*), and mosses.

The amplified warming of the Arctic has brought changes to the vegetation in all three tundra zones. In the low arctic zone, shrubs have been increasing at the expense of herbs and forbs. For instance, a study of vegetation changes in north-central Canada from 1984 to 2016 showed that the most significant trends were increased productivity in shrub-dominated environments.

High Arctic vegetation is found on the rest of the islands of the Canadian Arctic Archipelago, the northern half of the coastal regions of Greenland, Svalbard, and the northern edge of and Arctic islands of Eurasia. The High Arctic flora is reviewed by Zwolicki et al. These plant communities are the least diverse in the Northern Hemisphere and are dominated by cryptogams (mosses and lichens). Nevertheless, the High Arctic supports a greater variety of flowering plants than are found in Antarctica. There are almost 50 species of angiosperms in the High Arctic, which is polar desert. These plants grow low to the ground and occur as single, scattered individuals within mats of cryptogams less than 2 cm above the ground. Although the High Arctic regions are warming rapidly, the lack of soil moisture in most regions is a major factor limiting plant growth there.

Terrestrial Mammals

The Arctic regions are too cold to support reptiles and amphibians—only warm-blooded mammals and birds are found on these landscapes. Arctic tundra mammals are reviewed by Hope and High Arctic mammals are discussed by Elias. There are about 80 species of Arctic mammals, all adapted to life in extreme cold. Many species may be found in tundra across the Holarctic region, although only about a third of these are found exclusively on Arctic tundra. Most are either habitat generalists that are widespread throughout the northern latitudes, or they are predominantly boreal forest dwellers whose ranges extend north onto the tundra. The endemic Arctic tundra mammals are year-round residents, although many species are less than fully active in winter. They undergo either hibernation or torpor in the coldest months of the year. Hibernation is a voluntary state into which an animal enters to conserve energy, survive when food is scarce, and minimize the need to face the elements in the cold winter months. It is a truly deep sleep. Torpor is also a survival tactic used by animals to survive the winter months. Like hibernation, it also involves a lowering of body temperature, breathing rate, heart rate, and metabolic rate. But unlike hibernation, torpor is an involuntary state that an animal enters as the conditions dictate. Hibernation generally lasts many weeks or months. Torpor lasts only short periods. Arctic mammals have evolved in response to multiple glacial/interglacial cycles through the last 2.6 million years (the Quaternary period). They have developed life histories that reflect changing associations with other species and other biomes through time. However, the current warming of the Arctic is at a rate and magnitude that is approaching the limits of what tundra mammals have experienced at any time through the history of this biome. The continued persistence of Arctic tundra mammals will depend on the resilience and plasticity of adaptations among the species. One option that will no longer be available to them will be to migrate North in response to warming. Since even the High Arctic is warming, there is no cooler region for them to go. There are already indications there are changes afoot in the distribution of northern mammals. For instance, there is good evidence that indicates that the range of the arctic fox (*Vulpes lagopus*) has been retracting in the circumpolar tundra zone, while the red fox (*Vulpes vulpes*) is expanding its range northwards into the Arctic. Red foxes are one-third larger than arctic foxes, and the former has been observed interfering with arctic fox breeding dens in the Siberian tundra. The red fox is not as well adapted to cold as the arctic fox, but as the Arctic regions become warmer, the adaptation to extreme cold becomes less important.

Another example of a mammalian response to Arctic warming concerns the polar and grizzly bears of Canada. Since 2006, eight bears have been found in the Canadian Arctic Archipelago that are hybrids between grizzly bears (*Ursus arctos*) and polar bears (*Ursus maritimus*). DNA tests of tissues taken from these bears confirm their hybrid status. Until recently, grizzly bears have rarely been seen far north of the coast of mainland Canada, but since the 1990s there have been multiple sightings of grizzlies on arctic islands as much as 500 km north of the mainland.

Conclusions

The current environmental changes in the polar regions are happening at a pace and an amplitude hitherto unknown in these regions. Scientists are trying to keep track of the changes, and their effects on polar biota. Global warming from anthropogenic GHG emissions is probably having the greatest impacts on Arctic and Antarctic environments. In the Arctic, the interactions between land, sea, and ice are serving to amplify the warming, and all but the most stringent scenarios to reduce GHG emissions will very likely lead to a complete transformation of Arctic environments. It is already clear to see that the sea ice of the Arctic Ocean and adjacent seas will be gone in a few decades at most. No one knows just how the Arctic biota will respond to these environmental changes, but modeling efforts point to a breakdown of existing ecosystems.

Antarctica has not yet experienced the dramatic warming trend seen in the Arctic. However, Antarctic ice sheets are melting, albeit slowly, thus far. The total weight of ice loss averaged 43 gigatons per year from 1992 to 2002. Since then the melting has accelerated five-fold, to an average of 220 gigatons per year from 2012 to 2017. Ice loss from the West Antarctic Ice Sheet (WAIS) is known to be driven by changes in ocean melting of ice shelves in the Amundsen Sea. A study by [Holland et al. \(2019\)](#) has revealed that the most likely cause of this ocean melting is enhanced import of warm Circumpolar Deep Water onto these ice shelves, driven by a change in wind patterns. These patterns have been changing on a decadal scale, but in recent decades the conditions that cause warm water anomalies have become much more frequent. Current climate model projections show that if atmospheric GHG concentrations continue to increase as they are now, the warm ocean anomalies will become the norm by 2100, accelerating the loss of ice from the WAIS.

But the climate of Antarctica is not warming across the continent. Studies have shown that the climate is actually cooling toward the center of the continent, with the area of strongest cooling at the South Pole. Other regions are undergoing warming, with the greatest amelioration along the Antarctic Peninsula. A study by [Bromwich et al. \(2013\)](#) found that from 1958 to 2010, the average temperature at Byrd Station (80°S latitude) rose by 2.4 °C. Thus, a locality which is in the heart of the West Antarctic Ice Sheet is one of the fastest-warming places on Earth. However, as we have seen, most of the biota associated with Antarctica are residents of sub-Antarctic islands or live in the Southern Ocean. Unlike the Arctic, so far there is no evidence of a decline in Antarctic sea ice cover. This bodes well for the organisms in the marine food web.

Life near the poles is tough but vulnerable. The very adaptations that allow both marine and terrestrial life to survive the bitterly cold winters and short, cool summers can become liabilities in a rapidly warming world. Ecological patterns and long-term species associations are already starting to break down in some Arctic regions. Thus far, the marine biota of Antarctic waters has not

experienced such high rates of environmental change, but incursions of warm water caused by changes in wind patterns and ocean circulation will wreak havoc if they melt the sea ice and cause changes in krill distribution patterns.

One aspect of polar science that has cropped up repeatedly in data reports and review papers is a plea for additional observations on regional climates, oceanographic conditions, and the state of the polar biota. The polar regions remain remote, difficult to reach, expensive to study, and technically challenging to research. Nevertheless, we must make the effort to collect more data on these topics if we are going to come to grips with the changes now occurring in the Arctic and the Antarctic.

Abstract

Tundra exists in unglaciated parts of polar regions where it is too cold for the establishment and survival of trees. The primary climate control is summer temperature, but other factors can be important. Tundra is widespread in high latitudes of the Arctic, and is also found in some areas of Antarctica, notably the Antarctic Peninsula and islands surrounding the continent. Treeless alpine vegetation similar to tundra exists even in tropical latitudes provided that mountains are high enough and conditions hence sufficiently cold. The altitude and latitude of polar and alpine treelines is highly variable across the planet, reflecting controls on summer temperature by latitude and continentality, as well as regional and local factors including snow cover, slope and aspect. There is evidence that treelines, tundra and alpine vegetation environments are responding to the warming climate; shrub invasion into Arctic tundra and thawing of Arctic permafrost are notable examples.

Introduction

The term “tundra” is generally accepted as originating from the Finnish word “tunturia”, meaning barren land devoid of trees. Tundra vegetation is primarily comprised of grasses, sedges, dwarf shrubs, wildflowers, mosses, and lichens. The existence of tundra is primarily the result of temperatures during the growing season being too low for trees to become established and survive. Reflecting the fundamental control on temperature by latitude, tundra is a characteristic of polar environments. The boundary between tundra and forest is termed the polar treeline. The latitudinal limits of tundra broadly align with a mean July surface air temperature of around 10 °C (50 °F) and growing-season soil temperatures between 5 °C and 8 °C (41–46 °F) (Körner and Paulsen, 2004), just above the minimum temperature (5 °C) required for tissue formation in plants (Körner, 2008).

Tundra can be divided into Arctic and Antarctic tundra. Arctic tundra covers large areas of northern Canada and Russia, parts of Alaska, Greenland, Iceland and northern Scandinavia (Walker and Raynolds, 2018) (Fig. 1). It also covers the unglaciated parts of the Antarctic continent and surrounding islands. Because of the low moisture-holding capacity of the atmosphere in cold, polar latitudes, regions of tundra are also regions of generally low precipitation; some areas are characterized as polar desert and support only sparse vegetation. Tundra is also associated with permafrost—perennially frozen ground with an active layer that thaws and re-freezes on an annual basis and has strong impacts on vegetation. Despite low precipitation, tundra environments may be rather wet at the surface with thaw lakes. This reflects poor drainage (due to permafrost) as well as limited evapotranspiration (due to small energy inputs to the surface and sparse vegetation).

Treeless landscapes are also found in alpine regions in all latitudes of the planet where the elevation is sufficiently high and conditions hence sufficiently cold. This includes the Tibetan Plateau, sometimes referred to as the planet’s Third Pole as well as the highest altitudes of Mauna Loa and Mauna Kea in Hawaii. This is also true of the higher reaches of Mount Kilimanjaro, lying just north of the equator and also home to one of the world’s few remaining tropical glaciers. While similar to tundra vegetation in some respects, the vegetation above alpine treelines is viewed as sufficiently different that the term “alpine vegetation” is more appropriate than tundra, and that nomenclature is adopted here. Permafrost need not underlie regions of alpine vegetation, but parts of the Tibetan Plateau are underlain by permafrost. Precipitation on some alpine vegetation zones can be quite high, while it is meager in others.

Thermal conditions associated with treelines, whether they be polar or alpine, are not just a function of latitude and elevation, but are determined by proximity to marine influences, termed continentality, how much area surrounding individual peaks lies at high elevation (mass elevation effects), as well as local influences such as slope and aspect. Factors such as precipitation, winds, tree

Fig. 1 Distribution of Arctic tundra types. From Walker, D.A., Raynolds, M.K. (2018). *Pre-ABOVE: Circumpolar arctic vegetation, geobotanical, physiographic data, 1982–2003*. Oak Ridge, TN, USA: ORNL DAAC. 10.3334/ORNLDAAC/1323.

species and disturbance can also play a role, as can harsh winter conditions that can damage trees (Peregrine and Payette, 1998). While soil physical conditions, nutrient availability, carbon and nitrogen uptake and other biotic and abiotic factors can also influence treelines, there is ongoing debate as to their importance in comparison to the dominant control by summer warmth (Muller et al., 2016).

There is growing evidence that in response to recent climate warming, treelines are beginning to advance poleward and climb in altitude. Shrubification—an encroachment of woody plants into tundra regions, has been especially noticeable in the Arctic. However, both observed and anticipated treeline responses to climate change are complex and cannot be simply viewed as responses to rising summer temperatures.

Tundra and Treelines

General Features

Tundra is commonly viewed as synonymous with the Arctic environment. However, as is evident in Fig. 1, in many areas boreal forest extends well north of the Arctic Circle, such as over much of Siberia, northwestern Canada, and Alaska. By contrast, in other regions, notably over north central Canada, southern Baffin Island and northern Labrador, tundra extends well south of the Arctic Circle. There is a general correspondence between the southern limit of Arctic tundra depicted in Fig. 1 and the location of the 10 °C (50 °F) July isotherm at the surface in July (Fig. 2). The location of the 10 °C July isotherm is itself a function of large-scale controls by features of the atmospheric circulation and continentality, along with regional to local influences such as elevation and proximity of the land to cold or warm ocean currents.

The large-scale atmospheric control is the tropospheric circumpolar vortex. The circumpolar vortex can be broadly thought of as comprising the region of cold polar air north of the polar front jet stream; the jet stream is the dividing line between cold polar air and warmer air to the south. The vortex generally dips to the south over the Canadian Arctic Archipelago and into Labrador and as such, summer temperatures are especially low in this part of northern North America (in meteorological parlance, the region typically sits within a longwave trough). The interiors of Alaska, Canada, and Eurasia, by contrast, are isolated from ocean moisture

Fig. 2 The north polar region showing the location of the average 10 °C July isotherm at the surface. CIA World Factbook (free use under Public Domain).

sources and moderating marine influences on temperature, and hence have continental climates characterized by a large seasonal range in air temperatures. Winter temperatures can be bitterly cold. However, continentality means that summers are warm enough to maintain the treeline north of where it would be expected simply considering latitude.

The Brooks Range, which runs broadly west to east across northern Alaska, is an interesting example of topography controlling the treeline. Trees can exist on the southern (and south facing) side of the Brooks Range (at lower elevations) but cannot exist on the northern (and north facing) side. The Brooks Range also acts as a topographic barrier, preventing cold Arctic air from spilling southward. Hence, there is a very sharp difference in summer temperature at similar elevations just north and south of the Brooks Range (Serreze et al., 2001).

In Norway, the existence of trees well north of the Arctic Circle is explained by ocean circulation—the North Atlantic Drift Current, which brings warm water from the south into the Arctic, maintains much milder climate conditions than would be expected on the basis of latitude alone. Ocean influences also help to explain the existence of tundra on the Labrador Peninsula of Canada. While as noted, there is a large-scale control here by the tropospheric circumpolar vortex, the cold Labrador Current also keeps summer temperatures considerably lower than would be expected for this latitude. Because the Labrador Peninsula has a much more marine climate than central Canada and also lies at fairly high elevations (much of the area is a plateau), tundra extends south to 53°N. Similarly, proximity to cold ocean waters helps to explain why the Aleutian Islands of Alaska (not shown in Fig. 1) are almost completely treeless.

Forest-Tundra Ecotone (Treeline)

The transition between the Arctic tundra, where summer temperatures are too cold for trees to exist, and the boreal forest that lies to the south, is seldom abrupt. Rather, there is a transition zone, or ecotone, of varying width between the two biomes. In this sense, the term “treeline” is perhaps misleading. In northwestern Canada, for example, the transition zone, or ecotone, averages 145 km in width, widening markedly from west to east (Timoney et al., 1992). Fig. 3 captures the character of the ecotone on the south side of the Brooks Range in Alaska during April, photographed by the author while traveling north along the Dalton Highway, which largely parallels the Alaskan oil pipeline. In this case, the latitudinal control on the limit of trees is conflated with the altitudinal control; while there are still trees (black spruce) in the foreground, the mountains in the background, where temperatures are lower, are covered by tundra vegetation. As noted, trees cannot exist on the north side of the Brooks Range under the present climate.

Polar Desert

Arctic tundra is far from uniform; Fig. 1 clearly shows that there are many different categories that are reflective of the variety of climate conditions, soils, nutrient availability drainage and other factors. While it is not the objective of the present review to dwell upon the different tundra types, it is important to acknowledge that tundra generally becomes more “severe” the further north one goes, which makes sense given the fundamental control on tundra by summer temperature. The most extreme Arctic tundra landscape is known as polar desert, found in the Canadian Arctic Archipelago, parts of coastal Greenland (such as Peary Land on the north coast), and the Russian island of Novaya Zemlya. In an analysis of different polar desert sites in the Canadian Arctic Archipelago, L.C. Bliss (1997) recorded only a 2–3% plant cover, rising to 25–35% in favored areas where snowbanks provide meltwater.

Fig. 3 The forest-tundra ecotone on the south side of the Brooks Range of Alaska, as photographed by the author during April.

Fig. 4 Average daily surface air temperature, average daily maximum and minimum surface air temperature, and average monthly precipitation at station Alert, northern Ellesmere Island, Nunavut, Canada. Government of Canada.

Stones and fine sediments are often organized as patterned ground such as rings and stripes. Polar desert tundra environments are characterized by very cold winters, very cool summers and—as the name polar desert implies—scant precipitation.

The station Alert, located on the northern end of Ellesmere Island at 82.5°N in Nunavut, Canada, is a good example of a polar desert environment. **Fig. 4** shows monthly mean temperature, average daily temperature maxima and minima, and average monthly precipitation at the site. The daily average temperature during the warmest month of July is only 3.4 °C (38 °F) while daily highs are typically around 6 °C (43 °F). Average daily lows in July are just above freezing, while those in the neighboring months of June and August are below the freezing point. Thus, the growing season is quite short. The tundra is underlain by permafrost and snow covers the ground for >40 weeks per year. Because of low precipitation, the winter snowpack is quite shallow; values of 300–500 mm are typical of the area ([Serreze and Barry, 2014](#)). Annual precipitation at Alert averages only about 160 mm. While essentially all precipitation during the cold season is in the form of snow, snow can fall even during summer. As is typical of polar desert regions, precipitation is least during winter and peaks during summer; the peak at Alert, in July, is about 30 mm. The seasonal cycle in precipitation closely follows the seasonal cycle in column integrated atmospheric water vapor, which in turn reflects the control on saturation vapor pressure by temperature. With more water vapor in the atmosphere in summer, there is simply a greater likelihood for precipitation to fall, provided that the mechanisms are in place to cause uplift and condensation of air parcels ([Serreze and Etringer, 2003](#)).

Antarctic Tundra

Most of Antarctica is covered by glacial ice and the climate is extremely cold and arid, indeed, more arid than polar desert sites in the Arctic. However, tundra does exist on unglaciated coastlines and on Antarctic and sub-Antarctic islands. The Antarctic is home to two flowering plant species, Antarctic hair grass and Antarctic pearlwort, and areas of exposed rock may support lichens. More vegetation is supported on the unglaciated parts of the Antarctic Peninsula. The famed Dry Valleys of Antarctica have been studied as a possible analog to the environmental processes on the surface of Mars. The Dry Valleys represent one of the world's most extreme deserts and to call this inhospitable area tundra, which implies vegetation such as grasses and sedges, would seem to be a stretch. Endolithic (living inside rock) photosynthesis bacteria as well as anaerobic bacteria have been found in the Dry Valleys ([Barnett et al., 2007](#)).

Alpine Biome

General Features

The alpine treeline, representing the boundary between alpine vegetation at higher elevations and forest at lower elevations, varies greatly with respect to latitude and with regional to local factors that control temperature, modulated by influences such as the duration of the seasonal snowpack, winds, precipitation and soils. As noted, the regions of treeless alpine vegetation are not necessarily underlain by permafrost. Recall that the Arctic treeline is not abrupt - rather it is a transition zone, or ecotone, from boreal forest to tundra. In the same sense but on a smaller scale, the alpine treeline is usually a transition zone, but can be fairly abrupt in some cases. Within the transition zone, trees are commonly stunted and deformed by cold and windy conditions. This zone of stunted

Fig. 5 The alpine treeline at Craigieburn, New Zealand. Courtesy of Ellen Cieraad, Institute for Environmental Science at Leiden University.

trees is referred to as “krummholz”, a German word for “crooked wood”. **Fig. 5** provides a good example of an alpine treeline in New Zealand.

Variations in Alpine Treelines

It has long been observed that alpine treelines in the Southern Hemisphere tend to be at lower elevation than those in the Northern Hemisphere. Countering the idea that the difference relates to the types of trees found in the Southern Hemisphere, a more probable explanation is that at similar latitudes, summers in the Southern Hemisphere are generally cooler than those in the northern half of the planet. This reflects the landmass distribution—much more of the Southern Hemisphere is covered by ocean, meaning a stronger ocean influence in general, leading to cooler conditions (Cieraad et al., 2014). While alpine treelines in both hemispheres are associated with about the same summer air temperature, the critical air temperature in the Southern Hemisphere below which trees cannot exist is found at lower elevations.

As an example of regional variability in the Northern Hemisphere, the alpine treeline lies at about 4600 m (15,000 ft) in southeastern Tibet, while only 650 km to the east, it drops to 3600 m (11,800 ft) in the Balang Mountains. On a more local scale, in the Northern Hemisphere, treelines on north-facing slopes tend to be lower in elevation than those on south-facing slopes. This is because solar radiation receipts are lower on north-facing slopes and the snowpack takes longer to melt, which means a shorter growing season for trees (Peet, 2000).

The climate at the summit of Mount Washington (6288 ft or about 1900 m), the highest peak in the White Mountains of New Hampshire, near the northeast coast of the United States, provides an interesting example of an alpine vegetation environment. **Fig. 6** shows the annual cycles of temperature and precipitation at the Mount Washington Observatory, at the summit of the mountain. For ease of comparison with station Alert, **Fig. 6** uses the same vertical scales as **Fig. 4**. The treeline in the White Mountains, while ragged, lies at around 1400 m (4,500 ft). Mount Washington is part of the Presidential Range, and all the peaks in this range lie in the alpine zone. Reflecting latitude, air temperatures for all months are considerably higher than for the polar desert site Alert. The average temperature in July at the Mount Washington Observatory is close to 10 °C (50°F), with a typical daily highs of 12 °C (54 °F) and typical daily lows of about 8 °C (46 °F). Nevertheless, the growing season is short, and the use of monthly averages hides the fact that even in July, temperatures can fall below the freezing point. The record lows for June, July and August at the Observatory are -13 °C, -4 °C, and -7 °C (8 °F, 24 °F and 20 °F) respectively.

An interesting aspect of the Mount Washington alpine climate is that precipitation is quite high in all months; precipitation at the summit for the driest month (~160 mm in January) is almost as great as precipitation at the Alert polar desert site for the entire year. The annual total at the Mount Washington Observatory is just shy of 2500 mm (97 in.). The ample precipitation reflects the combination of the much higher atmospheric water vapor content compared to Alert (related to both temperature and proximity to the Atlantic Ocean), the frequent passage of storms (Mount Washington is located at the convergence of several storm tracks) as well as orographic uplift—forced uplift, cooling and condensation of moist air parcels.

At the landscape and local level, winds can have a significant effect on alpine treelines (Holtmeier and Broll, 2010). Winds generally increase with elevation in the middle and higher latitudes and as such, the treeline tends to be a windy place. While winds can greatly deform and stunt trees, they can also disperse seeds, bury trees under snow drifts, and scour slopes bare of snow. Winds also increase transpiration and evaporation, leading to the drying of soils. Strong winds can hence lead to conditions unfavorable for

Fig. 6 Average daily surface air temperature, average daily maximum and minimum surface air temperature, and average monthly precipitation at the Mount Washington Observatory, New Hampshire, United States. Mount Washington Observatory.

trees and can delay or even preclude the establishment of seedlings. In this context, another notable aspect of Mount Washington is its extremely high wind speeds. Average winds are high in all months and most notably, peak winds in all months are at least those of a Category 4 hurricane. The fastest wind speed ever recorded on Mount Washington was 103 m per second (231 mph).

It is instructive to compare conditions at the summit of Mount Washington to the conditions in the Tetons, about 3000 km to the west, at the southern gateway to Yellowstone National Park. Despite being at similar latitude, the treeline in the Tetons lies at roughly 3050 m (10,000 ft), more than twice as high as Mount Washington. This difference is due to the effects of continentality discussed earlier. While winters are cold, and winds are certainly fairly high in the alpine zone, continentality means that summers are warmer than one would find in a marine-influenced environment at the same latitude.

Another effect that relates to the higher treelines in the western interior of the United States, compared to the east, is that large areas surrounding individual peaks also lie at fairly high altitudes. Viewed most simply, the elevated land surrounding the peaks acts as an elevated heating source, resulting in what is termed a mass-elevation or Massenerhebung effect. The “mass” in this context refers to of the size of the area surrounding a given mountain that lies at a significant elevation above the surrounding plain. The greater the area, the greater the mass elevation effect. The mass elevation effect can be defined as the temperature difference at given elevation between inside and outside of a mountain mass. A completely isolated peak would hence not experience a mass elevation effect. This concept was first introduced by [De Quervain \(1904\)](#) to explain the observation that treeline and snowline occur at higher elevations in the central European Alps than on their outer margins. The Massenerhebung effect is now recognized to exist in many parts of the world ([Barry, 2008](#)), the Rocky Mountains being a notable example. The mass elevation effect in the Rocky Mountains averages about 1.8 °C, with the largest values in Colorado and in the basins of southern Wyoming ([Wang et al., 2017](#)). On continental or regional scales, the alpine treeline altitude can be viewed as related both to geographical location (latitude and longitude) and to the Massenerhebung effect, with the relative influence of these factors being strongly scale- and region-dependent ([Han et al., 2012](#)).

The Massenerhebung effect is, however, more complex than a simple elevated heat source. [Flohner \(1953\)](#) proposed that the summer warmth of elevated plateau surfaces results from the altitudinal increase in solar radiation and the relative constancy of net longwave radiation (incoming minus outgoing) with height, a hypothesis supported in subsequent studies. One argument here is that condensation, precipitation and cloud cover will tend to be greatest along the flanks of the mountain mass, leaving the interior with less cloud cover and hence stronger receipts of solar radiation. [Barry \(2008\)](#) argued that vegetation boundaries extending to higher elevations in the central Alps are related primarily to a shorter seasonal snow cover duration. With less snow cover, more solar radiation is absorbed at the surface, translating into a longer and warmer growing season. [Flenley \(2007\)](#) suggested that the Massenerhebung effect could partly be the result of a high dose of ultraviolet radiation due to reflection from clouds.

Along the west coast of the United States, in the Olympic Mountains of Washington State where the climate is strongly influenced by proximity to the Pacific Ocean, the treeline is again quite low in elevation (around 1500 m, or 4900 ft). The reason for the low elevation of the treeline here is similar to that of Mount Washington, which is also strongly marine influenced. However, an important driver in the Cascades is very heavy winter snow that buries trees until late summer.

Fig. 7 Average daily surface air temperature, average daily maximum and minimum surface air temperature, and average monthly precipitation at the Mauna Loa Observatory, Hawaii, USA. Mauna Loa Observatory.

Finally, consider the climate at the summit of Mauna Loa Hawaii (4169 m, or 13,678 ft), as recorded at the Mauna Loa Observatory (Fig. 7). As is the case for the neighboring and slightly taller shield volcano Mauna Kea, the summit of Mauna Loa lies in the alpine zone. In contrast to climates of both station Alert and Mount Washington, Mauna Loa experiences only a small range in average temperatures over the year. This is characteristic of low latitude mountains, where the annual ranges of incoming solar radiation and day length are small. Snowfall is not uncommon in winter, and there is occasionally enough to ski. However, precipitation for all months is fairly small. The contrasts between the situations at Alert (Fig. 4), Mount Washington (Fig. 6) and Mauna Loa (Fig. 7) serve to illustrate the remarkable variety of climates in which arctic tundra and alpine vegetation can be found. The common thread between these sites is the lack of summer warmth.

Tibetan Plateau

The Tibetan Plateau spans approximately 1000 km north to south and 2500 km east to west and has an elevation exceeding 4500 m (14,800 ft). It is surrounded by high mountain ranges, including the Hindu Kush to the west, the Himalayas to the south, the Kunlun Mountains to the north, and the Qilian Mountains to the northeast. As noted, The Tibetan Plateau is sometimes referred to as the earth's Third Pole. The plateau becomes progressively higher and drier to the north and northwest, where altitudes exceed 5000 m (16,000 ft). On the north and northwest side, annual precipitation is only 100–300 mm, similar to that of polar desert. Much of the plateau is characterized as montane grassland. However, permafrost is extensive, and parts of the plateau, such as the Qinghai-Tibet Plateau (Wang et al., 2011), are characterized by an alpine-like environment.

Effects of Climate Change

Recent warming is leading to expansion of woody plants in many areas of the Arctic and alpine, a process termed shrubification (Mod and Luoto, 2016). Arctic permafrost temperatures are rising, and permafrost is thawing, but with large variability from region to region (Romanovsky et al., 2010). Areas of thawing ice-rich permafrost are undergoing thermokarst, characterized by a highly irregular surface of marshy hollows and small hummocks. To the south, woody vegetation has advanced into alpine meadows in the southeastern Qinghai-Tibet plateau, the headwater regions of the Yangtze and Yellow rivers (Baker and Moseley, 2007; Wang et al., 2011). Warming in the Qinghai-Tibet plateau has largely paralleled the warming pattern of the whole country (Wang et al., 2007).

While tundra and alpine ecosystems are arguably among the most sensitive to climate change (Christensen et al., 2004), it is increasingly recognized that both observed and anticipated responses of tundra, alpine environments and treelines to climate change will be far from uniform across the globe and will involve much more than increases in summer temperature (Holtmeier and Broll, 2005). For example, a number of studies link observed treeline advances to winter warming (Harsch and Bader, 2011), acting to reduce winter stress on trees and improve recruitment. As an example of regional influences, in a study of northern

Quebec-Labrador treelines, Payette (2007) found contrasting responses to recent climate change depending on geographic position relative to the Labrador Sea. Along the coast, the northernmost latitudinal and altitudinal treelines responded positively to warming over the previous 50 years with spruce invading several tens of meters above the current treeline into the tundra. By contrast, white spruce treelines across the wind-exposed Labrador plateau, located much higher in altitude, receded a few tens of meters beginning around AD 1740–1750 and have not yet recovered. Adding to this complexity, while it is expected that the warming climate will affect species diversity and composition, the increase in the abundance of woody plants will further alter vegetation by modifying biotic interactions (Mod and Luoto, 2016). Non-climatic factors can also be important, such as topographic conditions. In Northern Europe, treeline positions are often controlled not so much by climate, but by herbivores (Cairns and Moen, 2004).

In short, while continued global warming is certainly expected to facilitate the advance of trees into higher altitudes and higher latitudes, sensitivities will vary by region and responses will likely involve a range of time scales. As to what tundra and alpine environments will look like 100 years from now, there are no simple answers.

Abstract

Soils of the Arctic region occur in one of the coldest parts of the Earth. Therefore, their development is dominated by cryogenic processes, resulting in unique soil properties. In soil classification the permafrost-affected soils are called Gelisols in the USA and Cryosols in Canada. The term Cryosol is also used in the international World Reference Base of soil (WRB) whereas in the Russian soil classification scheme these soils are not recognized as a separate order. Cryoturbation in the active layer is the most important process in turbic permafrost-affected soils. The soils in the Arctic sequestered large amounts of organic carbon and stored this carbon in the subsoil for thousands of years. Most of this carbon is still in a frozen state but has started to be released into the atmosphere as greenhouse gases due to climate warming. These released greenhouse gases in the Arctic then further accelerate the global warming in other parts of the world.

Introduction

The Polar Regions surrounding the North and South poles include most of the global permafrost regions (Nuttal, 2005). These regions are known as the Arctic in the Northern Hemisphere and as Antarctica in the Southern Hemisphere. Small permafrost areas can be found globally in high mountain terrains. Since the regions around the poles have the Earth's coldest climates, most of their soil materials are perennially frozen and their development is dependent on the amount of moisture in the soil and the stability of the landscape (French, 2007). In this article the focus is on the nature of soils in the Arctic.

Since about the last two decades Arctic soils are investigated because of climate change (Kimble, 2004) and because huge amounts of soil carbon are stored in these soils (e.g., Ping et al., 2008; Tarnocai et al., 2003a, 2009; Hugelius et al., 2013). To raise awareness on polar soils the Soil Atlas of the Northern Circumpolar Region was published and made available (Jones et al., 2010).

Northern Circumpolar Region

The northern circumpolar region is characterized by permafrost in most parts. Permafrost is defined as soil or rock that remains at or below 0 °C for at least two consecutive years (French, 2007). Permafrost is continuous in large areas of the Arctic and usually the terrain is associated with patterned ground (Fig. 1). The northern circumpolar soils cover approximately 19×10^6 km² and about half of this area is associated with permafrost and thus perennially frozen soils (Fig. 2) (Tarnocai et al., 2003b). South of this area the landscapes are characterized by seasonally frozen soils. Russia and Canada are the countries in the Northern Hemisphere with the largest areas covered with perennially and also seasonally frozen soils (Goryachkin and Karavaeva, 2004; Tarnocai, 2004a; Mikhailov, 2016).

Short, cold summers and long, extremely cold winters characterize the climates of the polar region. Mean daily temperatures above 0 °C occur only during the warmest part of the summer. Total annual precipitation is generally low and occurs mostly as snow (Nuttal, 2005). The common vegetation associated with the northern circumpolar soils is a conifer forest in the southern part of this region and, moving northward, north of the treeline, a shrub-tundra grading into a sparse vegetation cover. The ecosystems of the Arctic are very vulnerable. They are most influenced by climate change but during the last years also by tourism (e.g., Broll et al., 2003).

Fig. 2 The map shows the distribution of permafrost-affected soils (blue color) in the northern circumpolar area (Tarnocai et al., 2003b).

Soil-Forming Processes and Soil Characteristics

Soil genesis starts with weathering of the solid or loose parent material. Weathering processes are slow in the Arctic. Physical weathering including frost weathering takes place mostly at the surface. The dominant chemical weathering process in these soils is oxidation. Clay mineral formation is limited (Van Vliet-Lanoe et al., 2004; French, 2007).

The active layer is the layer of the ground in areas underlain by permafrost which thaws during summer (French, 2007). The active layer protects the underlying permafrost. The thickness of the active layer is controlled by soil texture and moisture, thickness of the surface organic layer, vegetation cover, aspect, and latitude. In perennially frozen soils, the active layer normally extends from 25 to 120 cm below the soil surface (Tarnocai, 2008).

Soil formation in the northern circumpolar region is dominated by cryogenic processes, which are driven by the presence and mobility of unfrozen soil water as it migrates towards the frozen front, along the thermal gradient in the frozen system. These processes, which produce a dynamic landscape, include freeze-thaw, cryoturbation or frost churning, frost heave, cryogenic sorting, thermal cracking, patterned ground and ice segregation (Van Vliet-Lanoe et al., 2004; Bockheim, 2015). Cryoturbation, which is very common in this region, results in irregular or broken soil horizons, involutions, organic intrusions (Fig. 3), organic matter build-up in the subsoil (often with concentration of this material along the top of the permafrost table), oriented rock fragments, silt-enriched layers, and silt caps (Bockheim and Tarnocai, 1998). Cementation very often results in characteristic soil structures, for example platy structure (Smith et al., 1991). Permafrost-affected soils contain various amounts of ice in the form of ice crystals, vein ice, ice wedges, and massive ground ice several meters thick (Fig. 4).

Particle size distribution in perennially frozen soils ranges from silty clay to coarse, gravelly sand. The composition of the fine-earth fraction is commonly dependent on the mode of deposition of the parent material (Tarnocai, 2008). The acidity in these soils varies greatly and also depends on the chemistry of the parent materials. The similarity of pH to that of the parent material is caused, in part, by cryoturbation, which not only mixes parent material with soil materials, but also mixes soil material among the horizons (Tarnocai, 2008). The nutrient content of perennially frozen soils is generally low since most of these nutrients are locked into compounds contained in the surface organic layer (e.g., Broll et al., 1999). Salt crusts, which form by translocation of salts from the subsurface horizons, develop during dry periods in the summer because of increased evaporation from the soil surface. Such salt crusts are common on the surfaces of High Arctic soils. Calcareous crusts on the underside of rocks are also a common phenomenon, especially in coarse-textured soils. Soils developed on fine-textured marine sediments usually have both high conductivity and high salt content (Tarnocai, 2008).

Fig. 3 Overview of frost action in soils. Cryoturbation is displayed by the strongly contorted mineral and organic horizons.

Soil Genesis and Soil Classification

The northern circumpolar soils generally have high moisture content, especially near the permafrost table, so beside cryoturbation gleying, associated grayish colors and redoximorphic features develop on most landforms, including those on better-drained positions. These soils are very often saturated because the active layer (the upper layer of the soil that freezes and thaws annually) is shallow. Thin, eluvial or leached horizons and brunification associated with coarse-textured soils are common in soils in the southern part of the discontinuous permafrost zone, but very seldom occur in the northern regions (Tarnocai, 2008).

Northern circumpolar soils are called Cryosols in Canada (Tarnocai, 2004b) and Gelisols in the USA (Ahrens et al., 2004). The World Reference Base of Soils (WRB) adapted the term Cryosol as well (Tarnocai et al., 2004). Russia developed an individual system for classifying the permafrost-affected soils (Mazhitova, 2004). Following the U.S. soil taxonomy Turbels are the dominant soils covering approximately $6.5 \times 10^6 \text{ km}^2$. The second most common soils are the Histels ($2.7 \times 10^6 \text{ km}^2$) and followed by the Orthels ($1.1 \times 10^6 \text{ km}^2$). In the Canadian classification the Cryosols are distinguished in Turbic, Static and Organic Cryosols. Seasonally frozen soils occur commonly in the southern part of the northern circumpolar region and these are dominantly Inceptisols, Spodosols, and Histosols (Ahrens et al., 2004; Tarnocai et al., 2003b).

Earth hummocks and hummocky terrain are characteristic for those sites in the landscape where there is enough fine soil material and enough moisture during summer. Earth hummocks are related to cryoturbation in most cases (Fig. 5) (Tarnocai and Zoltai, 1978) but can also develop due to eolian processes as so-called turf hummocks (Fig. 6) (Broll and Tarnocai, 2002). The hummocky terrain shows different physical and biological characteristics (Müller et al., 1998, 1999).

Soil Organic Carbon and Climate Change

Soils in the northern circumpolar region contain the single largest component of the terrestrial carbon pool. An estimate made by Tarnocai et al. (2009) shows that organic soils (Histosols and Histels) and perennially frozen cryoturbated mineral soils (Turbels) have the highest organic carbon contents ($32.2\text{--}69.6 \text{ kg m}^{-3}$) (Fig. 7).

Organic carbon pools estimated by the same authors also shows that the perennially frozen soils in the northern circumpolar region contain approximately 191.3 Pg for the 0–30 cm depth, 495.80 Pg for the 0–100 cm depth, and 1024.00 Pg for the 0–300 cm depth. Carbon pools in depths deeper than 300 cm were estimated to be 407 Pg for yedoma deposits and 241 Pg for deltaic deposits. Therefore, based on these estimates, the soils in the northern circumpolar region contain 1672 Pg of organic carbon with approximately 88% occurring in permafrost-affected soils and deposits. This 1672 Pg of the northern circumpolar region carbon accounts for approximately 50% of the total below-ground global organic soil carbon. This total is greater than the amount of carbon stored in the atmosphere or in the biosphere (Tarnocai et al.,

Fig. 5 Hummock in the Canadian Low Arctic, Turbic Cryosol. Photo Tarnocai, Sketch: From Müller G, Broll G, and Tarnocai C (1998) Soil temperature regimes in Baffin Island soils and their relationship to soil properties and microrelief. In: Lewkowicz AG and Allard M. (eds.) *Proceedings 7th International Conference on Permafrost*, pp. 771–776. Quebec: IPA.

2009). Because of the global significance of this soil carbon, research was carried out by soil scientists and ecologists especially on the decomposability of this soil carbon producing carbon dioxide and methane due to temperature increase (e.g., Knoblauch et al., 2013; Schuur et al., 2015; IPCC, 2019).

The global importance of soils in the polar regions was only recently recognized, when the role they play in global climate change was discovered. It is now widely accepted that climate warming has been, and will continue to be, much greater in both the northern and the southern circumpolar regions than in other parts of the globe with great effects on carbon cycling (e.g., Tarnocai and Broll, 2008; Tarnocai et al., 2009; Ping et al., 2015; IPCC, 2019). Changes in carbon cycling and carbon leaching have long been known, due to agriculture and fire in cold regions. In both cases the vegetation cover is destroyed, and the permafrost table moves downward (Fig. 8). Nowadays climate warming is the main reason for thawing of the permafrost as can be recognized throughout the Arctic (Fig. 9).

Fig. 7 Soil organic carbon mass of Cryosols in the northern circumpolar area (Tarnocai et al., 2003a).

Conclusion

Soils of the circumpolar regions are the coldest soils on Earth. These soils have been studied since the mid-1900s, but these studies greatly accelerated during the last two decades. There is now considerable knowledge of the processes that led to the formation of these soils, and of their role in relation to the unique ecosystems of the Arctic. However, their global significance was only recently recognized when the role they play in global climate, due to the huge amounts of organic carbon they stored for thousands of years due to their unique processes and properties.

Fig. 8 Left: In case of a natural vegetation cover organic carbon stays within the active layer. It is affected by cryoturbation and partly it is accumulated at the permafrost table. Right: Due to agriculture or fire leaching and decomposition of organic carbon is going on.

Abstract

Permafrost underlies the tundra of the circumpolar North. The landforms of permafrost regions are formed from the development or thawing of ground ice. The most ubiquitous features in tundra lowlands are ice-wedge polygons, the irregular nets of three- to seven-sided units at the surface of the landscape. The boundaries of the polygons are ice wedges, developed in cracks that open at temperatures below -10°C as the ground contracts in winter. The little, conical, ice-cored hills that occur in some tundra landscapes, pingos, are the iconic landforms of permafrost terrain. They develop as growing ice deforms the overlying permafrost, either in drained lake basins, as the unfrozen ground in the former lake bottom freezes back, or at the base of hillslopes where hydraulic pressure may supply water to maintain ice growth. Landforms associated with thawing permafrost are also prevalent in the tundra because permafrost degradation may be initiated by local disturbance as well as climate warming. Thermokarst (thaw) lakes are common features of ice-rich terrain. They commonly expand laterally at a relatively steady rate, but the rate of deepening reduces over time. Retrogressive thaw slumps form where ice-rich permafrost is exposed by erosion of lake shores, riverbanks, and at the coast. These slumps develop rapidly and have become especially prominent in landscapes that contain buried glacier ice remnant from the last glaciation. Development of all these features has been affected by climate change enhancing the probability of near-surface permafrost thaw.

Introduction

The principal landforms of the tundra biome are closely associated with the presence of permafrost. They represent deformation of the terrain due to growth or melting of ground ice. Permafrost, ground that remains at or below 0°C for 2 years or more (ACGR, 1988), is a product of climate. At the continental scale its two most important drivers are air temperature and winter snow cover. Permafrost underlies almost all the terrain in the tundra biome because of the low air temperatures, low snow-holding capacity of the vegetation, and absence of trees to prevent drifting of snow. Ice-wedge polygons, perhaps the most ubiquitous landform in tundra lowlands (Fig. 1), are generated by low winter ground temperatures due to these factors (Mackay, 2000). Pingos, the iconic little hills of some tundra regions, are most abundant in sandy sediments of drained-lake basins after permafrost has aggraded into them (Fig. 2) (Mackay, 1979).

The top of permafrost in unconsolidated sediments is characteristically ice rich, so that if the ground ice melts, the ground surface will subside or, on hill slopes, may fail. Such thawing leads to development of thermokarst terrain, the pitted relief that results from melting of ground ice (Burn, 1992). Thermokarst lakes are common in much ice-rich ground and are now of interest for their association with climate change (Fig. 3). Permafrost degradation beneath them occurs in an anaerobic environment, leading to production of methane when organic matter previously entombed in frozen ground is thawed and decomposed (Walter et al., 2006). Retrogressive thaw slumps, landslides that are common after exposure of ice-rich permafrost, develop the most rapidly of all landforms in the permafrost landscape (Fig. 4) (Burn and Lewkowicz, 1990). They have become increasingly common in the last 20 years as air temperatures and rainfall totals have risen in the Arctic (Kokelj et al., 2015; Lewkowicz and Way, 2019).

Fig. 2 Ibyuk Pingo within its drained lake basin near Tuktoyaktuk, NWT, Canada. Photograph by C.R. Burn.

Above permafrost is a surficial layer of ground that thaws each summer called the active layer. A hummocky micro-relief commonly develops in active-layer soils which contain enough silt and clay to be frost susceptible (Fig. 5) (Tarnocai and Zoltai, 1978). Hummocks are associated with a buried ice-rich organic layer at the top of permafrost that is also a potential source of greenhouse gases when permafrost thaws (Mackay, 1958).

Hummocks

Hummocks are circular mounds about 1 m in diameter with a relief of up to 20 cm (Fig. 6). Mud hummocks (Fig. 5) are features for which the intensity of frost action and, perhaps, climatic conditions prevent establishment of vegetation on the ground surface. Earth hummocks, in contrast, have a continuous vegetation cover (Fig. 6). Hummock centers are composed of mineral soil, but

Fig. 3 Thermokarst lakes on Richards Island, western Arctic Canada (see [Burn, 2002](#)). Photograph by C.R. Burn.

Fig. 4 Retrogressive thaw slumps developed above Canoe Lake, Richardson Mountains, Canada. The slumps have developed in ice-rich deposits remnant from the last glaciation. The limit of glaciation is visible on the hillside, at the lowermost extent of visible bedrock. Photograph by C.R. Burn.

the small troughs between adjacent features are filled with organic material ([Fig. 7A](#)). Consequently, the active layer beneath the center of the features is deeper than in the troughs and the frost table is bowl shaped ([Figs. 6 and 7B](#)).

The hummock form is maintained by soil circulation, with upwelling in the middle of each feature, movement to the periphery, and the soil flux continuing downward toward the frost table and toward the lower parts of the bowl ([Mackay, 1980](#)). The circulation is perpetuated by ice segregation at the top and bottom of the hummock in autumn and early winter, with ice lenses growing parallel to the ground surface with downward freezing or to the top of permafrost by up freezing causing a small lateral displacement of soil. As these lenses thaw in spring and summer, soil settlement results in a net outwards movement near the surface and inwards movement at depth ([Mackay, 1980](#)). Upward movement in the center of the hummock is necessary for continuity of

Fig. 5 Mud hummocks, western Arctic coast, Canada. Photograph by the late J.R. Mackay.

Fig. 6 An earth hummock in tundra on Richards Island, western Arctic coast, Canada. The dowel rods have been inserted to the frost table. circulation. This may be facilitated by high moisture content at the base of the hummock's active layer in summer lowering soil density and promoting diapiric movement. In some environments, similar features are known as *frost boils* due to soil near its liquid limit emerging at the surface. Sorted circles of coarse clasts also develop in a similar manner (Fig. 8).

The circulation moves surface organic material to the peripheral edges of the hummocks and then carries some downwards into the base of the feature (Fig. 7A). Since the porosity (percentage of total volume that is pore space) of organic material is greater than mineral soil, less saturated organic material may thaw over the summer than proximal mineral soil. The downward movement of organic material by soil circulation is a prime cause of substantial buried organic materials beneath hummocks (Fig. 7A), and the high porosity of organic material is one of the reasons for the high near-surface ice content of hummocky terrain (Fig. 7B). The ice content is enhanced by ice segregation during up freezing, with gradual addition of organic-rich sediment at depth leading to an ice-rich zone beneath the hummocks that may be over 1 m deep.

Fig. 7 (A) Cross-section of an earth hummock, showing the central mineral soil surrounded by brown (thawed) or black (frozen) organic material; (B) earth hummocks showing the ice-rich top of permafrost beneath them and the bowl-shaped frost table (see Mackay, 1980). Photographs by the late J.R. Mackay.

Fig. 8 Sorted circles of frost-shattered bedrock, Bunker Hill, Yukon, Canada. The centers of the circles have a soil matrix, but the peripheries are composed of stones and rocks. Photograph by C.R. Burn.

Destruction of surface vegetation by forest fire or other disturbance leads to a deepening of the active layer, thawing of ice-rich permafrost, and flattening of the hummock micro-relief (Mackay, 1995). As vegetation subsequently re-establishes, aggradation of permafrost and growth of ice lenses in the basal bowl shape squeezes the hummock from below and re-establishes its micro-relief (Kokelj et al., 2007).

Ice-Wedge Polygons

Polygonal ground is a ubiquitous feature of terrain underlain by unconsolidated sediments in the tundra biome (Figs. 1 and 9) (Mackay, 2000). Tundra polygons have long been widely recognized in lowlands and other flat terrain, but they also occur on hill slopes (Mackay, 1990a). They are characteristically 15–20 m wide in lowlands and may possess 3–7 sides (Fig. 9A). On hill-slopes and uplands they may be considerably larger, with widths up to 40 m (Fig. 9B). LeCompte (2004) digitized aerial photographs of more than 3400 polygons near the Canadian western Arctic coast and found the average area of lowland polygons was 309 m² ($n = 1998$) and of upland polygons was 796 m² ($n = 1480$). The polygons are bounded by a network of shallow troughs that in lowlands commonly lie between two ridges, one in each adjacent polygon. Some polygons are subdivided by troughs so that the primary features may be composed of smaller secondary or even tertiary units (Fig. 10) (Mackay, 2000). The troughs are underlain by V-shaped wedges of massive ice, whose development establishes the polygonal network (Fig. 11).

Our understanding of ice-wedge formation and growth was established by E. de K. Leffingwell after almost a decade of field studies in the early 20th century on the northern coastlands of Alaska and has been well developed theoretically by Lachenbruch (1962). However, the most comprehensive field investigations that have led to our current understanding of both the polygons and

Fig. 9 Ice-wedge polygons in (A) lowland and (B) upland settings Richards Island, western Arctic coast, Canada. The polygons in drier upland settings are larger than the polygons in the wet lowlands (see [Mackay, 1990a](#)). (A) Photograph by Sam Cornish and (B) photograph by C.R. Burn.

their bounding ice wedges were published by J.R. Mackay from field studies near the western Arctic coast of Canada, especially on Garry Island and at the experimentally drained lake basin, Illisarvik, on Richards Island (Mackay, 2000). At Illisarvik, Mackay examined the development of these features from their inception (Mackay, 1986), while at Garry Island he was able to assess their long-term behavior based on nearly 40 years of measurements (e.g., Mackay, 2000).

Ice-Wedge Development

The ice wedges that bound the polygons are among the few diagnostic indicators of permafrost (Fig. 11). Their origin was interpreted by Leffingwell after living for several winters on the tundra, where he heard sudden loud noises accompanied by a shock sufficient to rattle dishes in a field cabin. Subsequently, he found open cracks in hard-packed snow that penetrated the ground (Fig. 12). He pointed out that in spring, meltwater may infiltrate the cracks and freeze to form a vein of ice or, alternatively, hoar frost crystals may grow in the crack from saturated vapor. The cracks originate in response to thermal stress (tension) that develops as the ground cools after freezing of the active layer (Lachenbruch, 1962). Cracking is repeated at the same location because the ice vein is a locus of weakness in the ground, with the fracture commonly originating at the top of permafrost. Repeated cracking, infilling with meltwater, and freezing leads to the growth of the ice wedges. Over time, growing ice wedges incrementally push the bounding permafrost apart, creating troughs at the ground surface.

Several observations of the temperature of frost cracking indicate that the ground is below -10°C when it yields by brittle failure (Fortier and Allard, 2005). Lachenbruch (1962) indicated that cracking occurs during relatively rapid decreases in ground temperature, normally provoked by a cold snap at the surface. Mackay's (1993) observations generally confirm this, but he noticed variation in cracking temperatures between new wedges at Illisarvik and established forms at Garry Island. Following the initial rupture, the ice-wedge crack may widen to release further stress if the ground cools and it may propagate along the trough. Presumably, widening of the crack will be accompanied by deepening but this has not yet been reported from the field. In spring, the cracks may close as the ground warms before snow melt, so the long-term rate of ice-wedge growth (mm a^{-1}) is normally less

Fig. 12 Thermal contraction crack in the floor of Illisarvik experimentally drained lake from the first winter after drainage, 1978–79. The crack is about 4 cm wide (see Mackay, 1986). Photograph by the late J.R. Mackay.

than the annual crack width (cm). Cracking may not occur during winters in which the ground cools insufficiently or if thermal stress is relieved by cracking of other wedges.

Polygon Rims

While a trough develops over a growing ice wedge, the ground on either side may be raised to create a rim around each polygon (Fig. 13). Development of these bounding ridges is to accommodate the volume of the growing ice wedge, the growth of peat, the formation of ice in the rims from water sourced in the trough during freezing, and lateral compression during expansion of permafrost and the active layer in summer. The latter process transports soil from the polygon center to the rims, at a rate measured on Garry Island in 1966–79 of $0.4\text{--}0.6\text{ cm a}^{-1}$ (Mackay, 2000). Net outward movement is possible because contraction is confined

Fig. 13 Ridges on sides of ice-wedge troughs and depressed polygon centers, Tuktoyaktuk Peninsula, western Arctic coast, Canada (see Mackay, 2000). Photograph by C.R. Burn.

in winter, but in summer expansion may occur into the trough. When ice wedges crack frequently and ground deformation is in progress, the polygon centers are lower than the ridges, but not the troughs. These polygons are known as low-centered. Low-centered polygons may evolve into high-centered polygons if the wedges cease cracking and peat growth raises the center. If ice wedges thaw, the troughs become deep, the ground becomes well drained, the ridges collapse, and the polygons become distinctly high-centered (Mackay, 2000).

Polygon Development

Mackay (1974), studying the western Arctic coastlands of Canada, noted the development of a polygon network in a well-drained former lake basin within 10 years of drainage, but he did not find any networks at poorly drained sites in 100 years since drainage. No networks of polygons have evolved at Illisarvik since drainage in 1978 (Mackay, 2000). Growth of vegetation in the lake basin at Illisarvik has led to increased snow depths, increases in ground temperature and cessation of initial thermal contraction cracking (Mackay, 1986). Where networks have developed in drained lake basins, the polygons have commonly been irregularly organized. However, in the flood plain of a migrating river or if a lake shrinks in its basin the polygons are commonly quadrilaterals and have cracks parallel and perpendicular to the moving water body (Lachenbruch, 1962).

The primary hypothesis for evolution of the polygon network from a lattice of primary troughs to subdivision of polygons with secondary and tertiary troughs attributes the smaller troughs to infrequent cracking during severe winters. The hypothesis is weak because it does not consider changes in the thermal regime of ice-wedge troughs as a result of ridge development, which in turn reduces the probability of cracking by increasing local snow depths and ground temperatures. The hypothesis may also be criticized as the expansion of cracks over winter releases further incremental thermal stress, and therefore a primary network may respond by itself to a range of thermal conditions. It appears that historical factors associated with trough and ridge/rim development may weigh considerably in network evolution. On hillslopes, where down slope movement of the active layer hinders ridge development, and other settings where ridges do not develop well, the networks have few secondary troughs.

Pingos

Pingos are the iconic little hills of tundra environments that have a core of ice and, like ice wedges, are diagnostic of permafrost (Fig. 14). The name of these features comes from an Inuktitut word for conical hill. They are rarely more than 50 m high and are characteristically circular in plan form, with dilation cracks running along their crest lines from separation of the ground on either side of the feature as it rises upwards and steepens. The basal circumference of pingos may vary over orders of magnitude from tens to hundreds of meters. They are found in two principal settings, (1) where the ice core is fed by ground water under hydraulic pressure to raise the open-system type, or (2) where the uplift is from expansion due to freezing of water in confined ground, such as a drained lake basin, to create closed-system pingos. The former type is found in Greenland and Svalbard where hydraulic pressure is generated in proximal ice caps (Liestøl, 1996), while the latter are most well-known from the western Arctic coastlands of Canada (Figs. 2 and 14) (Mackay, 1979, 1998).

Closed-System Pingos

The closed-system forms are found in drained lake basins of Arctic plains, where permafrost has grown into formerly unfrozen sediments (Fig. 2). They are primarily restricted to sandy ground (Mackay, 1973). Lakes are found in Arctic plains, even in coarse grained sediments because seepage is impeded by the surrounding permafrost, so water may collect in depressions. Unfrozen ground is normally found beneath water bodies of sufficient depth to remain unfrozen at the bottom for most of the year, because over the year the temperature there is on average $> 0^{\circ}\text{C}$. The unfrozen ground surrounded by permafrost is known as talik. If a lake drains, as has been reported from many locations (Jones and Arp, 2011), the sediments will be exposed to the atmosphere and permafrost will aggrade into the talik.

Permafrost aggradation into sandy sediments is characterized by expulsion of water from freezing ground in order to accommodate the volume expansion as water turns to ice. For sands of porosity 0.3, there is almost a 3% increase in total volume as a result of freezing, and this is entirely in the pore water. Since permafrost aggradation occurs downwards from the ground surface and laterally from the permafrost surrounding the talik, the water expelled during freezing is confined in the remaining unfrozen ground and its pressure will increase (Mackay, 1973). Commonly, the expelled water will have a freezing-point depression associated with solutes in the groundwater that have been excluded from the ice and expelled ahead of the freezing front. Hence the talik may remain unfrozen at temperatures $\leq 0^{\circ}\text{C}$.

The pressure within the talik continues to increase until water is released to the surface through a fracture or the talik freezes through (Mackay, 1977). However, pressure development may lead to deformation of the surface, especially in an area of relative weakness. Such sites are likely to be associated with residual ponds in the lake basin, which reduce permafrost aggradation directly beneath them. Where deformation occurs, the uplift of the ground has a volume equivalent to the supporting pore water, which forms a lens of water in the talik just below the frozen ground. The water lens gradually freezes, creating a core of ice for the deformed ground (Fig. 15). The volume of deformation is equivalent to the volume of excess pore water. The initial deformation establishes the footprint of the pingo, but growth continues as further permafrost aggradation supplies more water to the water lens. The uplift rate of a pingo varies along the side of the feature with distance from the pivot point at the base of the pingo (Mackay, 1979, Fig. 19). The highest rates of growth, over 20 cm a^{-1} , have been measured at the tops of pingos (Mackay, 1979).

Pressures measured in the water lens have been equivalent to the weight of the overlying frozen ground and ice lens (Mackay, 1977). Artesian flow occurs when water lenses are punctured. If the drill hole is on the side of the pingo, geysers have gushed upwards (Fig. 16), but when the drill hole is on top of the pingo the water flows out over the ground surface, confirming the equivalence of water and overburden pressures. The pressures that develop by freezing are sufficient to support features that are as large as Ibyuk Pingo near Tuktoyaktuk, the largest pingo in Canada, almost 50 m high. Given the 15 m overburden of Ibyuk Pingo and the 35 m of ice above the water lens, and that Ibyuk Pingo has been growing recently (Mackay, 1979), the pressure in its water lens is about 6 atm.

The growth rate of a pingo depends on the expulsion of water during freezing and its rate of addition to the water lens. Permafrost aggradation occurs at a rate that declines over time as the distance between the cold ground surface and the point of freezing increases. The rate follows the Stefan relation, discussed below, where z (m) the depth of freezing is related to time, t (a):

$$z = b \sqrt{t} \quad (1)$$

the constant, b , depends on the thermal conductivity of frozen soil, the mean annual surface temperature, and the latent heat of fusion for pore water in the sands (Mackay, 1979). The nature of the relation was validated by Mackay (1990b, Fig. 9) who

Fig. 15 Pingo ice exposed on the coast of Tuktoyaktuk Peninsula, western Arctic Canada. Photograph by the late J.R. Mackay.

Fig. 16 Geyser on a pingo from a punctured water lens, Tuktoyaktuk Peninsula, western Arctic Canada (see Mackay, 1977). Photograph by the late J.R. Mackay.

examined the successive thickness of annual growth bands in pingo ice and showed a very close fit between band width and Eq. (1) where t is the time after ground freezing reaches the water lens.

The uplift of a pingo characteristically splits the feature so that the summit resembles a crater (Fig. 2). Multiple dilation cracks are common (Fig. 17). Dilation cracks may be filled with ice, similarly to ice wedges, although the crack is formed by upward movement of the frozen strata as well as thermal contraction. Some dilation cracks are continuous with thermal contraction cracks in the drained lake flats. At the base of the slopes, uplift may create a fracture in permafrost open to the water lens and groundwater may emerge at the surface. Alternatively, a subsidiary pingo may grow at such locations if the water ejected up the fracture is confined (Fig. 18).

Pingos may cease growth if the talik freezes, or they may collapse because of oversteepening of the sides or exposure of ice in the summit crater (Mackay, 1998) (Fig. 19). The collapse may take several years and may be arrested if exposed ice is covered by material slumping as the permafrost thaws. If the sides of the pingo become steep during its growth, soil may creep downhill to transfer ground materials within the footprint of the feature. When the feature subsequently collapses a circular rampart may survive (Fig. 20). The centers of collapsed pingos do not form deep depressions because the height of the pingo is due to the ice and water lenses. Once these lenses melt, the surface elevation is close to that of the original lakebed.

Open-System Pingos

In comparison with the research by J.R. Mackay on the closed-system pingos of the Tuktoyaktuk Peninsula area, there is relatively little documentation of open-system pingos and no survey of growth rate. There are several examples of these features known from Greenland and Svalbard (Liestøl, 1996), where they are thought to be fed by water originating from three sources: geologic faults, taliks beneath ice sheets and glaciers, and permafrost aggradation following emergence from the ocean due to isostatic rebound. In Svalbard, several pingos have water draining from the pingo throughout the year, creating substantial icings on the flanks of the features. High pressures are required to lift these pingos, as with the closed-system type. One example on Svalbard rises to 42 m above the valley floor.

Fig. 17 Dilation cracks on a pingo, Tuktoyaktuk Peninsula, western Arctic coast, Canada. Photograph by C.R. Burn.

Fig. 18 Collapsing pingo with subsidiary pingo that has grown beside it, Richards Island, western Arctic Canada. Photograph by C.R. Burn.

The ice core of an open-system pingo on Svalbard was a series of massive ice lenses rather than simply one massive icy body, as has been most commonly observed with the closed-system type (Yoshikawa, 1993). This indicates that growth of these features may be episodic and depend on the pressure emanating from the water source. Yoshikawa (1993) also suggests that conduits for water from sub-permafrost aquifers may become frozen, and new routes may open, leading to mounds of different ages growing inside each other (Liestøl, 1996). While closed-system pingos are characteristically circular or oval in plan view, the open-system type may be elongated and irregular in shape.

Thermokarst Lakes

Thaw lakes are water bodies that fill “a closed depression formed by settlement of the ground following melting of ground ice” (ACGR, 1988, p. 89). The lakes are common in ice-rich terrain throughout the permafrost zones, developing after disturbances

Fig. 19 Massive ice exposed in summit crater of a collapsing pingo on Richards Island, western Arctic Canada. Photograph by C.R. Burn.

Fig. 20 Remnant pingo rampart, Richards Island, western Arctic Canada. Photograph by Sam Cornish.

such as forest fires or climate change (Burn and Smith, 1990). The shape and depth of the lakes depend on the time since thawing began and the local distribution of ground ice. In ice-rich sediments, the lakes keep growing until the ground ice body is exhausted (Fig. 21).

The key thermal relations that maintain thermokarst development depend on lake water depth (Roy-Leveillee and Burn, 2017). If the water body is too deep to freeze to the bottom in winter, then the lake-bottom temperature will be above freezing year-round and thawing will proceed beneath the lake. Where surface ice reaches the lake bottom in winter, permafrost may be stable below the lake bottom even if annual mean lake-bottom temperature (T_{lb}) is above freezing, depending on the ratio of freezing to thawing degree days. This is due to higher thermal conductivity (λ , $\text{W m}^{-1} \text{ } ^\circ\text{C}^{-1}$) of frozen than thawed sediments, which affects the net heat balance of the lake substrate. If $T_{lb} < 0 \text{ } ^\circ\text{C}$, permafrost is expected beneath a lake-bottom active layer. In Canada's western Arctic coastlands, permafrost is preserved beneath water depths less than two-thirds of the winter ice thickness (Burn, 2002). In the lakes of Old Crow Flats, northern Yukon, permafrost degradation may occur beneath shallow water where snow accumulation on the ice surface affects the temperature, and hence the freezing degree days at the lake bottom (Roy-Leveillee and Burn, 2017). In warmer conditions of central Yukon, lake ice is thinner, and thawing appears to proceed at the edge of lakes (Burn and Smith, 1990). In lakes where the bottom remains unfrozen year-round, T_{lb} is characteristically $2\text{--}4 \text{ } ^\circ\text{C}$. As a result, thaw lakes provide the greatest local adjustment of ground temperatures in the permafrost regions from patterns determined by climate (Burn, 2002).

Fig. 21 Thermokarst lakes of Richards Island, western Arctic Canada. Photograph by C.R. Burn.

Lake Growth

Thaw lakes develop from an initial disturbance where the active layer deepens into ice-rich ground. Melting of excess ice leads to subsidence of the ground and creation of a depression where water may collect. The elevated water content increases the time required for freeze back and raises the mean annual ground temperature. The depression then becomes a locus for soil water that promotes further thawing. Additional subsidence will continue so long as the thawing permafrost is ice rich. The pond acts as an area of higher temperature on the ground surface, and while the surface is depressed, heat flows both downward and laterally into the surrounding permafrost. Consequently, horizontal and vertical expansion of the water body occurs.

Thaw of permafrost occurs at a rate that depends on the ice content of the ground, the temperature gradient between the lake bottom and the surface of permafrost, and the thermal conductivity of thawed lake sediments. Where a thaw lake is growing, the depth to permafrost and the depth of the lake increase over time, at a rate that diminishes as the temperature gradient declines. The depth of thaw (z) is governed by the Stefan equation (Burn and Smith, 1990):

$$z = \sqrt{\frac{2\lambda T_{lb} t}{\rho L}} \quad (2)$$

where the t is time since thawing began, ρ is the volume fraction of ice in permafrost, L is the latent heat of fusion (J m^{-3}), and other terms are as defined above, using the absolute value for T_{lb} . The annual rate of expansion of lake radius may be obtained from Eq. (2) by setting $t = 1$ a. Near Mayo, Yukon, field observations of both lateral expansion (0.5 m/year) and lake deepening have validated this relation in ice-rich ground (Burn and Smith, 1990). In some cases, lake growth leads to coalescence of lakes (Fig. 22), but in others it may lead to drainage (Mackay, 1988).

Lakes will continue to expand in ice-rich sediments until the local ground ice is exhausted. However, in sandy deposits the ice content may be close to the porosity of the sand and there is little subsidence as the ground thaws. Furthermore, sand-sized particles are less easily transported away from the lake edge, unlike silts and clays that may become suspended in the water during storms, and hence sand characteristically accumulates and stabilizes the shoreline. Many thaw lakes developed in sands have wide subsurface terraces that may support permafrost beneath shallow water around the lake edge (Fig. 3) (Burn, 2002).

Talik Configuration

The talik beneath a thaw lake represents a thermal disturbance that may be confined by perennially frozen ground or may penetrate through permafrost. The configuration of the talik may develop as described by Eq. (2), but in time it will reach an equilibrium state. In the simplest case, of a circular lake at equilibrium, the temperature T_z in the center of the talik at depth z beneath the lake is given by (Burn, 2002, Eq. 3):

$$T_z = T_g + \frac{z}{I} + (T_{lb} - T_g) \left(1 - \frac{z}{\sqrt{z^2 + R^2}} \right) \quad (3)$$

Fig. 22 One thermokarst lake formed from three, with lake ice floating above the central pool of each lake, Richards Island, western Arctic Canada. Photograph by C.R. Burn.

where T_g is the mean annual temperature of permafrost at the surface, I is the geothermal gradient in permafrost ($\text{m } ^\circ\text{C}^{-1}$), and R is the radius of the lake (m). Eq. (3) shows that while temperatures in the talik are sensitive to the lake-bottom temperature and conditions in the surrounding permafrost, they also depend on the size of the lake. Where R is large, temperature in the talik increases with depth following the geothermal gradient, and there may be no permafrost beneath the lake. For smaller values of R , the talik will be closed at depth, but the base of permafrost will rise beneath the body of unfrozen ground. Since regional temperatures in the ground and in lakes vary little, the width of thaw lakes is the principal local control on whether taliks are closed or penetrate permafrost. For given values of T_g and T_{lb} a critical radius can be calculated for which the temperature at any depth beneath the center of a lake $\geq 0^\circ\text{C}$. In Canada's western Arctic, critical R is approximately 200 m (Burn, 2002). Where there are littoral terraces, critical R is for the central pool of the lake, and diminishes as terrace width increases, because permafrost beneath the terraces has a higher temperature than in the surrounding terrain.

Lake Orientation

Many thaw lakes in the Arctic coastal plains of Canada, Alaska, and Siberia are elongated and aligned in a common direction. Some of the lakes are oriented in depressions eroded by ice sheets (Figs. 3 and 21), but many appear to be caused by wind-activated circulation of the lake water (Mackay, 1963). In the sandy plains of the western Arctic coastlands, the lakes are oriented perpendicular to the prevailing wind direction. This has been attributed to the movement of water in two cells from the windward shore to each end of the lake, then to the lee shore, and back across the lake. The current should be fastest at the ends of the lake because of the integrated flow along the windward shore. In contrast, in the silts and clays of Old Crow Flats, the elongation is parallel to the prevailing winds. The difference is due to the minimal erosion effected by cross lake currents in sediments that are generally not suspended in the lake water but accumulate at the site of wave action, and the substantial erosion that occurs when finer sediments may be suspended and removed from the lake shore (Roy-Léveillé and Burn, 2016).

Drainage

Disappearance or shrinkage of thaw lakes is generally by catastrophic drainage. This is caused by the following factors: (1) there is little sediment in surface water to fill lakes; (2) growth of vegetation is relatively slow in the tundra environment; and (3) there is only a short period for evaporation each year (Burn, 1992). On average, several lakes drain each year along the western Arctic coast of North America, perhaps in a period of hours (Jones and Arp, 2011). The rapid drainage is commonly initiated by spring melt-water impounded in the basin. The water overtops a snow dam and then erodes ice wedges or other ice-rich ground as flow is initiated. The rapid drainage means that the lake bottom is turned quickly from a lacustrine to a terrestrial surface beneath which permafrost aggradation begins the following winter.

Thaw Lake Cycle

Drainage of thaw lakes leaves a basin, perhaps containing residual ponds. Permafrost aggradation is initially rapid because of the absence of vegetation to trap snow, but the rate of aggradation slows with time as sedges and shrubs colonize the basin. With time, networks of ice wedges develop in these basins and some aggradational ground ice forms in the sediments. However, the extent of ground ice formation during the Holocene has been insufficient to raise the ground surface to its original elevation, and therefore restore the terrain to the conditions prior to initial thaw lake development. This means that while ice-wedge polygons, pingos, hummocks, and other features that depend on ground ice may form in these basins, renewed thaw lake development encompassing the whole basin does not occur, unless the drainage outlets become obstructed (Fig. 23). In sandy deposits, the margins of drained lake basins tend to be higher than the centers, but in finer-grained sediments, such as in Old Crow Flats, the centers are domed (Jorgenson and Shur, 2007; Roy-Léveillé and Burn, 2016). These relations are likely a product of the extent of intra-basin sediment transport that occurs due to variation in suspension of each particle-size type during storms. Finer-grained sediments are transported into the basin center, unlike sands that remain near the location of erosion (Roy-Léveillé and Burn, 2016).

Retrogressive Thaw Slumps

Thaw slumps have characteristically been the most rapidly developing landforms in the permafrost environment. They comprise a steep headwall of 20–90° angle, commonly with exposed massive ice, and a low-gradient foot slope. The foot slope is covered by debris that has fallen from the headwall and a slurry from ablation of the exposed permafrost (Burn and Lewkowicz, 1990). Thaw slumps are initiated by erosion that exposes ice-rich permafrost in riverbanks, lake shores, at the coast, or in a few cases by sliding of the active layer (Fig. 24). The headwall ablation of the features is commonly over 10 m a^{-1} . Supersaturated slurry may flow away from the headwall, even on slopes as low as 3 degrees. The features continue to develop until the headwall reaches ice-poor ground, fallen debris covers it, or the foot slope rises sufficiently to meet the terrain surface, thereby covering the headwall. Apparently stable materials in the foot slope may be remobilized by rainstorms that reactivate sediment transport out of the feature and prolong development of the slump. Stable features, especially along the Arctic coast, may also be reactivated by erosion at the water body removing surficial materials and providing a new base level for the feature.

Thaw slumping has been a focus of significant interest with the recent development of very large features, mega-slumps, that have headwalls over 25 m high and are over 1 km across, cover areas of up to over 52 ha, and have retreat rates up to over 25 m a^{-1} (Fig. 25) (e.g., Lacelle et al., 2015). Sediment from these features alters the chemistry of water courses, may dam the receiving creeks, and affects the sustainability of the streams as viable fish habitat (e.g., Kokelj et al., 2013). Mega slumps may be clearly visible on satellite images and have been mapped at subcontinental scale in close association with the limits of glaciation (e.g., see Fig. 4) (Kokelj et al., 2017). Many of the features are in relict glacial ice that has only recently yielded their development in association with climate change, particularly through increases in the number and intensity of rainstorms (Kokelj et al., 2015). Thaw-related factors, also enhanced by climate change, are well correlated with the widespread development of thaw slumps on Banks Island, Arctic Canada, where over 4000 features were initiated between 1984 and 2015 (Lewkowicz and Way, 2019).

Fig. 25 Mega-slump on Peel Plateau, NWT, Canada. The feature is over 1 km wide. Photograph by C.R. Burn.

Mega slumps are huge individual features in the permafrost landscape, a terrain that characteristically has had little sediment movement. Yet there are few depressions in the regions where the slumps are currently found to indicate a prior period of comparable thaw slump development. The early Holocene (~ 8000 years ago in the Arctic) was a period of exceptional warmth in the western Arctic, and unconformities representing greater active-layer thicknesses are visible in many mega-slump headwalls. It is possible that initiation of the slumps has required incision of the landscape by streams through the Holocene to develop slopes that have only recently been destabilized by climate change effects.

Conclusion

Many of the landforms of permafrost regions are directly associated with the growth or melting of ground ice. In the 20th century, most features were considered as part of an environment in equilibrium with its climate, and so growth or degradation of features was commonly associated with disturbances, i.e., the appearance of fresh substrates for permafrost aggradation or damage to

vegetation cover leading to permafrost degradation. In the 21st century, effects of climate change on the permafrost landscape have become widespread in regions with sufficient ground ice. Degradation of ice-rich ground is now widely reported. The surficial effects have been best observed in relatively cold environments, because the active layer there is thin and so a small-scale change requires little additional energy. In contrast, in regions where the active layer is thick, even though the permafrost may be considerably warmer, the permafrost landscape appears to be more resilient to climate change. As the climate shifts, it is difficult to foresee how any component of the geomorphological systems in the tundra biome will remain unaffected.

Abstract

Even though insects cannot regulate their internal temperature through metabolism, they manage to live in some of the coldest regions of the planet. They achieve this through a wide variety of adaptations. The active part of their life cycle is compressed into the few short weeks of Arctic summer. In order to build up the necessary nutrients and metabolic energy to fulfill their life cycle, most Arctic insects live several years, either in the larval or adult stage. Arctic insects avoid lethal polar winter air temperatures by seeking shelter beneath snow, inside plant tissues, beneath leaves or in mud. As summer turns to winter, polar insects prepare physiologically for freezing temperatures. Some species are freeze-tolerant, and others avoid freezing. Most Arctic insects are freeze-tolerant, meaning they allow ice to form inside their body cavities, but carefully control the location of ice crystals to avoid tissue damage. Freeze avoiding insects build up antifreeze chemicals in their hemolymph that allow their bodies to super-cool to temperatures well below the normal freezing point of water. Some small and soft-bodied insects that live in soil allow most of the water in their bodies to be drawn out into the soil as it freezes, and so avoid frozen tissues through desiccation.

Introduction

Insects, like other invertebrate animals, are poikilothermic. This means that they cannot regulate their own body temperatures except by behavioral means such as basking in the sun or burrowing in the soil. As [Everatt et al. \(2015\)](#) so succinctly put it, "Invertebrates, more so than any other animal group, are at the whim of their environment." Of course in regions such as the tropics, where temperatures are generally both warm and stable throughout the year, this aspect of insect physiology puts little or no environmental stress on insects. This is certainly one factor that contributes to the incredible diversity of tropical insects. However, seasonality and cold temperatures increase in the higher latitudes, and winter air temperatures become lethal to insects in the Polar Regions. There are very few insects living in Antarctica because of its ice cover. This article therefore deals primarily with insect adaptations for life in the Arctic.

Insects have many ways of dealing with cold climates. Surprisingly, the one adaptation that is not utilized by arctic insects is migration to lower latitudes during winter. Nearly all arctic insects and other invertebrates remain there throughout the year. Their behavioral adaptations are mainly focused on seeking shelter from winter air temperatures. Their physical adaptations include small body size and dark-colored exoskeleton. Their physiological adaptations include freeze resistance, freeze tolerance, and cryoprotective dehydration. Their life history adaptations include multiyear life spans, especially of larvae and adults, as well as adaptations in their phenology: the timing of periodic events in their life cycle. Each of these topics are discussed in some detail, below, after a brief discourse on the natural history of arctic insects.

Insect Life in the Polar Regions

The Arctic regions are generally inhospitable to insects and other invertebrates. The winters are very long and incredibly cold, with air temperatures that are lethal to insects persisting for several months of the year. Summers are short, and the length of the growing

season decreases with latitude. The growing season in arctic tundra regions averages 50–60 days. Regions far north of the Arctic Circle ($66^{\circ}33'N$), the High Arctic, have only sparse, intermittent plant cover (Fig. 1). Thus, the diversity of plant feeding insects, predators and scavengers is extremely low here.

An example of the physical environment of the High Arctic can be found in the Zackenberg valley, situated at $74^{\circ}28'N$ in northeast Greenland, as described in a study by Westergaard-Nielsen et al. (2017). Here, the mean annual mean temperature is about $-9.0^{\circ}C$. Mean July temperature is $6.3^{\circ}C$ and mean February temperature is $-19.8^{\circ}C$. As in most High Arctic regions, mean annual precipitation is less than 250 mm, of which approximately 85% falls as snow. Maximum snow depth is remarkably shallow, ranging from 0.13 to 1.44 m over recent years. In this valley, the growing season is 51 days. This represents the time of year when the ground surface is not frozen, so plants may grow. The High Arctic is a cold desert. A survey of the insect life of all the High Arctic regions by Hodkinson et al. (2013) found only 296 species. A survey of ground beetles of northern Canada (Ernst and Buddle, 2015) found that just four species: *Pterostichus haematopus*, *P. brevicornis*, *P. caribou*, and *Amara alpina* accounted for 44% of all beetles captured by pitfall trapping in the High Arctic. By comparison, the boreal forest regions of Canada have more than 32,000 insect species.

One useful measure of the biological productivity of an ecosystem is its Net Primary Productivity, or NPP. NPP is the rate at which all the plants in an ecosystem produce useful chemical energy; it is equal to the difference between the rate at which the plants in an ecosystem produce useful chemical energy (GPP) and the rate at which they use some of that energy during respiration. In the arctic tundra ecosystems, 87% of the estimated NPP is produced in the Low Arctic. For polar desert regions of the High Arctic, above-ground NPP ranges from 0 to 50 g per m^2 of surface area per year (Gould et al., 2003). Not surprisingly, the species diversity of insect orders is far greater in the Low Arctic than in the High Arctic (Danks, 1981) (Table 1). As shown in Fig. 2, the productivity of the High Arctic regions is less than a tenth of the productivity of the boreal and temperate regions. The productivity of mainland arctic tundra is about one-quarter of the productivity of the boreal forest and temperate grasslands.

Antarctica is even more inhospitable to insect life than the Arctic. In fact, there are very few insects living on the Antarctic continent. Ice-free areas cover only one-third of 1% of Antarctica. These rare ice-free areas include nunataks, which are mountain peaks and other rock formations exposed above a glacier or ice sheet. In recent years, these bleak, windswept exposures have been found to harbor invertebrate life, including springtails (Fig. 3). Springtails (Collembola) are primitive, minute, six-legged arthropods. Most of the invertebrates that live in Antarctica, including Protozoa, mites, nematodes, springtails and midges live in the moss beds and melt water lakes. The Antarctic fauna includes 20 species of springtails (Collembola), two species of midges (Diptera), and a number of parasitic insects that are associated with coastal birds and marine mammals, including 37 species of biting lice

(Mallophaga), 5 species of sucking lice (Anoplura), and 1 species of flea (Siphonaptera) (Gantait and Chandra, 2017). The flightless midge *Belgica antarctica* is the largest purely terrestrial animal in Antarctica, measuring up to 6 mm in length.

Arctic Insect Life Cycles

Because of the brevity of summer warmth in the Arctic, many insects are unable to complete their entire life cycle from egg to larva to pupa to adult in a single summer. They are forced to overwinter in one or more stages of their life cycle. Different groups of insects have different life cycle patterns. The life cycle of 23 ground beetle species (Carabidae) of dry and mesic, open tundra habitats in the Tromsø region of northern Norway was studied by Andersen (2013), who examined the reproductive period and the seasonal occurrence of larvae, teneral, and fully hardened adults. Teneral are the earliest stage of adult insects, immediately after molting. For a brief interval, their exoskeleton is soft and immature in coloring. He found that nine species breed in spring to early summer, have summer larvae and hibernate exclusively as adults. Nine species mainly breed from June to September, and in this group the larvae as well as adults hibernate. Insect hibernation is known as diapause. This is a period of suspended development in insects, during unfavorable environmental conditions. The beetles that undergo diapause as both adults and larvae frequently seem to need more than 1 year to complete their development. The species with winter larvae start to reproduce much earlier in the year in Northern Norway than do populations living farther south. Eggs and/or pupae as well as larvae and adults of three further species hibernate. Andersen estimated that the tiger beetle *Cicindela campestris* needs at least 3 years to fulfill its development in Tromsø. Arctic ground beetles are much more likely to have overwintering larvae than temperate zone species.

Fielding and Defoliart (2010) studied embryonic developmental rates in northern populations of grasshoppers (Table 2). In cold climates, these insects spend two winters in the egg stage. Prediapause and postdiapause embryonic developmental rates were measured in the laboratory over a wide range of temperatures for two species of cold-adapted grasshoppers: *Melanoplus borealis* and *Melanoplus sanguinipes* (Fig. 4). The authors fit a model to the data and used it to predict dates of egg hatch in the spring and prediapause development in the fall under different temperature regimes. Actual soil temperatures were recorded at several locations over 5 years. Laboratory environmental chambers were used to simulate climate warming, so that 2°C, 3°C, or 4°C were added to each hourly recorded temperature in the insects' natural habitat. The results suggest that a 2°C, 3°C, or 4°C increase in soil temperatures will result in eggs hatching 3, 5, or 7 days earlier than predicted, respectively (Table 2). An increase of 3°C would be required to advance prediapause development enough to allow for a portion of the population to complete its life cycle in 1 year. This 1-year life cycle in insects is called univoltine. In another experiment, 2°C and 4°C were subtracted from observed temperatures. The authors determined that a 4°C decrease in winter soil temperatures could delay hatching by 8 days.

Table 2 Observed median hatch dates and predicted hatch dates of *Melanoplus borealis* based on soil temperatures and developmental rates from laboratory

Years	Observed median hatch date	Predicted median hatch date	Differences in predicted hatch date (days) with altered temperature regime			
			−4° C	−2° C	+2° C	+4° C
2000	4 June	31 May	+8	+4	−4	−6
2002	28 May	30 May	+7	+3	−3	−5
2004	29 May	23 May	+8	+4	−3	−5
2006	1 June	3 June	+8	+4	−3	−6
2008	5 June	10 June	+8	+4	−3	−6

Danks (1981) presented an excellent review of this topic. Northern arthropods normally take one or more years for a generation. The proportion of species taking longer than 1 year to complete their life cycle increases with latitude. Relatively few high arctic species complete their life cycles in a single year. The duration of the life cycle also depends on habitat, since relatively rapid development is possible in warm microhabitats, such as inside plants or in warm shallow ponds. Slow life cycles can be attributed to reduced resources of heat and food. The fecundity of arctic insects tends to be low, with species from many insect groups producing only one or a few eggs per year. This low egg production is apparently due to a combination of factors, including short, cold summers, and poor food supply. In northern regions where food supply is abundant, either more eggs are laid per clutch, or eggs are laid two or three times during the summer.

Research in Iceland showed that there were two generations per year in the midge *Tanytarsus gracilentus*, a species that in the low arctic is univoltine, but in the high arctic takes several years to develop. The springtail *Hypogastrura tullbergi*, which took 3–5 years to develop in the High Arctic, completes a generation in only 2 months to a year in temperate regions. Some remarkably long life cycles have been demonstrated for various insect groups in the Arctic. Typical estimates are as follows. For arctic midges (Chironomidae), 2–7 years; for arctic crane flies (Tipulidae), 4 years or more; in northern horseflies (Tabanidae), at least 3 years; for high arctic tussock moths of the genus *Gynaephora*, 3–5 years; for high arctic scale insects (Coccidae), up to 5 years; for high arctic blow flies (Calliphoridae), 1–2 years; for high arctic spiders, up to 7 years. Life cycles typically are longest in larger insects.

Hågvar et al. (2017) studied the life cycles of nine species of cold-adapted ground beetles during a 2-year period in Norway. A 2-year (biennial) life cycle was documented for three of these species, based on the simultaneous hibernation of larvae and adults. In at least one species (*Patrobis septentrionis*), both larvae and adults showed considerable activity in winter, beneath the snow. The most cold-adapted ground beetle of the Northern Hemisphere, *A. alpina* and a near-relative species, *Amara quenseli* had larval hibernation.

The data indicated that some individuals might hibernate a second time and thus experience two egg-laying seasons.

Berman and Leirikha (2018) published a study of cold-hardiness in ants (Formicidae) that live in the coldest region of the Northern Hemisphere, in northeastern Siberia. Whereas nearly all ants in the temperate zone produce at least one brood of offspring per year, in northeastern Siberia the ant larvae develop very slowly, taking 2–3 years to complete this part of their life cycle. However, the limited super-cooling ability in the ants of the genus *Formica* prevents them from living in regions where winter air temperatures are colder than about -25°C , including the upper reaches of the Kolyma River and even more so in the upper reaches of the Yana and Indigirka rivers, where winter temperatures drop below -50°C .

A comparison of trapped adults of *A. alpina* and *Cymindis vaporariorum* in 2007 and 2008 showed that summer temperature regime plays a significant role in the timing of adult emergence and entering into diapause (Fig. 5). In 2007, both species had active adults on the landscape as early as May 30. Average monthly temperature rose from 4°C to 9.8°C between May and June that year. In 2008 the earliest appearance of adults for both species was during the interval of June 28–July 10. Average June temperatures that year were 7.8°C (Fig. 6). However, summer warmth in 2007 apparently ended by the end of August. Average August temperatures

Ecology of alpine carabid beetles (Coleoptera, Carabidae) in a Norwegian glacier foreland, with a special focus on claw wearing to indicate relative age. *Norwegian Journal of Entomology* **64**, 82–111.

Fig. 6 Mean summer monthly temperatures for the Finse, Ulvik region of Norway for 2007 and 2008. Data from the Norwegian Meteorological Institute (2018). *Climate statistics, Finse, Ulvik (Hordaland)*. <https://www.yr.no/place/Norway/Hordaland/Ulvik/Finse/climate.month09.html> (Visited August 1, 2018).

that year were 9.8°C, but fell precipitously to 5.3°C by September (Norwegian Meteorological Institute, 2018). In 2008 *A. alpina* remained active through the first 2 weeks of September, when the average temperature was above 9.5°C. Both species had a few individuals captured during winter months, most likely emerging from the snow during brief warm intervals.

The timing of events in an organism's life cycle is known as its phenology. The phenology of arctic insect life cycles tends to be pushed ahead in spring. For instance, arctic midges emerge as adults even before the lakes where they over-winter as larvae are ice-free. Soil-dwelling insects are able to remain active after the beginning of freezing temperatures because of the latent heat in the soil.

Melanism and Body Size

Most northern insects are darker in color and smaller in size than southern species. In species that have ranges that include both temperate and arctic regions, there are population differences. Northern specimens of these species are both smaller and darker than southern specimens. Melanism is an adaptive response that makes the most of limited solar warming in cold regions. Absorption of solar energy by the exoskeleton warms the insect's internal organs, facilitating activity at lower temperatures. The effectiveness of melanism is demonstrated by the fact that it is present in all genera of arctic butterflies, in addition to a reduction in size and basking behavior. Another example of melanism concerns arctic ground beetles. All of the species of arctic ground beetles in the *Cryobius* group of the genus *Pterostichus* have a black integument.

In larger insects, melanism is often combined with hairiness of the integument. Shiny hairs permit the entry of short-wave radiation but prevent the loss of heat accumulated by the dark surface of the insect. This heat would otherwise escape through the emission of long-wave radiation. This is essentially a biological example of the greenhouse effect. Most arctic insects are small by comparison with insects that live in warmer regions. For instance, the average body length of the 27 species in the northern *Cryobius* group of *Pterostichus* is 6.8 mm, compared to the overall average length of 12.4 mm for the 55 *Pterostichus* species from the temperate and boreal regions of North America (data from Lindroth, 1966). The exceptions to this are some large-sized arctic caterpillars, adult butterflies and bumble bees. All of these spend their time in or near protected microhabitats such as flowers and plant cushions. They are also dark colored and hairy, enabling them to trap solar energy.

Brachyptery

Brachypterous insects have very reduced wings, so that they are unable to fly. This is a common feature of some arctic insect groups. For instance, all of the *Cryobius* species of the genus *Pterostichus* are brachypterous (Lindroth, 1966). This structural modification has also been observed in arctic stoneflies, chironomid flies (midges), other beetle families, and ichneumon wasps (Danks, 1981). There are several theories concerning the reason for arctic insect brachyptery. In regions dominated by low summer temperatures, insect flight may be quite restricted. This is because flight muscles need to reach a certain temperature before they can function. If the necessary air temperatures are rarely or never reached in a given region, then winged flight becomes impossible, and wings become useless. The development of wings requires metabolic energy. If wings do not confer any advantage, then natural selection would favor flightless forms, because the latter may have more energy available for other life processes, including reproduction. Beetles have elytra, or wing covers, that must be raised before the flight wings beneath can be used. In flightless beetles, the elytra are often fused together, forming a more-or-less solid cover over the abdomen that allows heat to accumulate inside the abdominal cavity.

Behavioral Adaptations

Those arctic insects that do fly generally fly very close to the ground, where heat reflected from the soil creates a warm microhabitat. Resting adult insects often select particularly warm sites, such as locations with dark surfaces, as well as inside the heads of flowers that have a parabolic shape to trap solar energy. Basking in the sunshine is an important behavior for flying insects, as they need to warm their flight muscles before they can fly. Basking has been observed in the Antarctic midge, *B. antarctica*.

Temperature thresholds for development and activity are commonly very low in Arctic species. Development of many species of midges and mosquitoes has been observed taking place throughout the winter, even when the lakes remain ice-covered and the lake water temperature is close to freezing. Tundra species of shore bugs (Saldidae) and crane flies (Tipulidae) are active at 0.5°C (Danks, 1981).

Dietary Adaptations

Because of the short growing season and paucity of insect food resources, especially in the High Arctic some insect groups that are carnivorous in the lower latitudes have species that are either omnivorous or even herbivorous in the Arctic. As shown in Table 3, increasing latitudes in Canada are correlated with increasing omnivory and herbivory of ground beetle species (Ernst and Buddle, 2015). At Banks Island in the Canadian High Arctic, 69% of ground beetle species are omnivorous, while less than 1/3rd are strict predators. The most commonly found omnivore in the High Arctic is the opportunistically predacious granivore, *A. alpina*.

Table 3 Dietary composition of ground beetles and rove beetles in latitudinal transect of northern Canada

Locality	Latitude	Ecological zone	% Carnivores	% Omnivores	% Herbivores
Moosonee, ON	51.28°N	North Boreal	95	5	0
Schefferville, PQ	54.76°N	Subarctic	80	16	4
Churchill, MB	58.74°N	Subarctic	88	7	5
Yellowknife, NWT	62.52°N	North Boreal	81	6	12
Tombstone Mountains, YT	64.61°N	North Boreal	94	4	2
Norman Wells, NWT	65.29°N	Subarctic	84	2	14
Kugluktuk, NU	67.78°N	Subarctic	76	22	2
Cambridge Bay, NU	69.12°N	High Arctic	36	61	3
Banks Island, NWT	73.22°N	High Arctic	31	69	0

Data from Ernst, C.M. and Buddle, C.M. (2015). Drivers and patterns of ground-dwelling beetle biodiversity across Northern Canada. *PLoS One* **10**(4), e0122163.

In contrast to this, in boreal forest localities, such as Moosonee, Ontario, 95% of ground beetle species are carnivorous. In the High Arctic, the dietary flexibility of this otherwise predaceous beetle family gives them a better chance to survive in an environment that has only meager animal food resources.

Selection of Overwintering Sites

All arctic arthropods on land or in shallow waters are exposed to freezing temperatures for much of the year. Nevertheless, even in permafrost areas, overlying snow insulates against air temperatures that are lower still. Good protection beneath snow is available at tree line, and adults of the mosquito *Culiseta alaskaensis*, hibernating for example in snow-covered clumps of grass, experience temperatures no lower than -7°C to -9°C , and appear to lack cryoprotectants. Bottom sediments in shallow arctic ponds likewise are warmer than the air.

Pond temperatures of about -20°C occur in the coldest month at Barrow, Alaska (71°N) when mean air temperatures were about -33°C . Such temperatures probably persist for several months, and can be compared with temperatures not below -15°C in shallow ponds at Churchill (59°N) and, by analogy with soil measurements with temperatures of about -30°C at Lake Hazen in the Canadian High Arctic (82°N). Chironomid larvae in ponds at Barrow were killed by temperatures below -18°C . Larvae of the Antarctic midge *B. antarctica* did not survive temperatures much lower than -15°C (Baust and Edwards, 1979).

Oviposition (egg laying) of overwintering eggs on withered rather than green leaves by female butterflies, provide for a more sheltered winter site. Ovipositing high arctic mosquitoes select sites that have clear advantages for early spring egg hatch, and selection does not necessarily relate to winter conditions.

Some arctic species hibernate fully exposed on ridges swept free of snow by wind. The ground beetle *Amara glacialis* has been observed hibernating in small grooves excavated in the sand (and mainly prepared by the end of August), rather than penetrating to deeper layers. Such habits seem to correspond with the earlier amelioration of exposed sites in spring. Some other features of overwintering sites are not related to temperature. For example, the tremendous spate in spring in northern streams may carry away organisms that have overwintered in the substrate. However, this potential instability might be mitigated in arctic streams, except in the most superficial sites, by the fact that most of the run off would take place while organisms were still safely frozen into the stream bed. As a general rule, the overwintering stage is inactive (e.g., eggs) only in species of fairly stable habitats; then the overwintering site is selected by an earlier life stage. In many other species an active overwintering insect itself selects the overwintering site.

Only freeze-resistant and desiccation-resistant mosquito eggs can overwinter in the Arctic. These insects must complete their life cycle each year. Bumblebee colonies must develop sufficiently each summer to produce sexual forms, as only queens overwinter. Apparently most arctic insects overwinter in their larval stage. Very few insects overwinter as pupae in the High Arctic. On the contrary, the pupal phase is usually very short in arctic insects, especially species that pupate with the onset of spring.

It is well known that air temperature records in the Arctic fail to accurately describe the thermal conditions of sheltered microhabitats. This is particularly the case during winter, when snow cover insulates terrestrial habitats from extreme air temperature fluctuations. Surprisingly few studies have been done on the cold hardiness of High Arctic insects. One exception is a study carried out in Svalbard by Convey et al. (2015). They assessed the survival of High Arctic soil invertebrate communities contained in soil and vegetation cores when exposed to winter temperature variations. The overwintering temperatures the invertebrates experienced were manipulated by deploying cores in locations with varying snow accumulation: No Snow, Shallow Snow (30 cm) and Deep Snow (120 cm) (Fig. 7). Winter air temperatures at the study site fluctuated between -3°C and -24°C , and the No Snow soil temperatures matched air temperatures closely. Soil temperatures varied less under 30 cm of snow, and did not decrease below -12°C . Temperatures beneath deep snow were even more stable and did not decline below -2°C . Surprisingly, there were no clear differences in survival of the invertebrate fauna between the three sets of environments. The survivors included several groups of soil mites, spiders, springtails (Collembola), mosquito larvae, and beetles. The study demonstrated previously

Fig. 7 Soil (2 cm) and air temperatures at Endalen study site, Svalbard, from September 2012 to March 2013. Svalbard airport temperature data from Norwegian Meteorological Institute. Figure after Convey, P., Abbandonato, H., Bergman, F., et al. (2015). Survival of rapidly fluctuating natural low winter temperatures by high Arctic soil invertebrates. *Journal of Thermal Biology* **54**, 111–117.

undocumented tolerance of extreme cold temperatures for the spiders, mosquitoes, and beetles. These invertebrates were able to withstand temperatures as low as -24°C , as well as the series of the rapid, large scale changes of temperature. The research suggests that most of these taxa are highly cold tolerant.

Cold-Temperature Physiology

Cold-adapted insects are able to function at temperatures near freezing because of their unique physiological adaptations. Their body chemistry is geared to function at temperatures near or below freezing. For instance, coordinated neuromuscular activities have been observed in the cold-adapted ground beetle, *Pterostichus brevicornis*, at temperatures as low as -12°C . In cold-acclimated beetles, motor nerve fibers showed six different activity types, compared with only two types in warm-acclimated beetles. Indeed, feeding and ovarian development have been reported in these beetles during February, when temperatures were still well below freezing. The metabolism of cold-adapted insects has been observed to function at rates similar to those of temperate-zone insects living in moderate temperatures. Cold-adapted insects have evolved “cold-adapted” enzymes that facilitate chemical reactions at low temperatures (Georlette et al., 2004). Enzymes are organic catalysts, and the package of enzymes in cold-adapted insects have a high catalytic efficiency. However, this efficiency comes at a price: their effectiveness breaks down at higher temperatures. One might be tempted to think that cold-adapted insects would thrive in the kind of warm temperatures experienced in the temperate zone, but this is not the case. Because cold-adapted metabolism is facilitated by enzymes that work *only* at low temperatures, arctic insects exposed to temperatures above about $15\text{--}20^{\circ}\text{C}$ often die because of metabolic failure. Specifically, the weak stability of these enzymes at even moderate temperatures causes them to become ineffective and even break down (Georlette et al., 2004). Cold-adapted insects produce enzymes that have a specific activity at low temperatures that is up to tenfold higher than the enzymes in warm-adapted insects. This is the principal physiological adaptation to cold at the enzyme level. It compensates for the otherwise inhibitory effect of low temperatures on chemical reaction rates, providing the insect with sufficient metabolic activity to carry out its life cycle in frigid temperatures.

Recent studies have examined the unique aspects of metabolic regulation and cell preservation that facilitate natural cold hardiness. Because cold-hardy insects seek shelter beneath the surface (i.e., underneath snow cover, in frozen mud, under piles of plant debris), their access to atmospheric oxygen becomes limited. Furthermore, insects living in Polar Regions survive the winter either in their egg stage, or as overwintering larvae or adults that undergo diapause. Insect metabolism requires oxygen, but because environmental oxygen is limited or unavailable to overwintering insects in cold regions, they must be able to cope with anoxia. Oxygen requirements fall as insect metabolic rates slow during diapause. Winter survival of cold-adapted insects is enhanced by active suppression of energy-expensive cell functions, including mitochondrial activity. However, survival in oxygen-poor or oxygen-starved environments does not include the suppression of all biochemical functions. There is up-regulation of the hypoxia inducible factor, HIF-1, to coordinate responses that provide hypoxia protection and prevent loss of hemolymph flow to vital organs. This involves increased cellular response to molecular stimulus due to an increase in the number of receptors on the cell surface. Overall, the studies summarized by Storey and Storey (2010) show that cold hardy insect species use a suite of dynamic responses to modulate cellular metabolism in response to seasonal, low temperature, and freeze/thaw cues.

Acclimation and Cooling Rates

The difference between summer and winter temperatures is quite large in many parts of the Arctic and Antarctic. On exposed surfaces, temperatures can vary by as much as 100°C between seasons. A few invertebrates, such as the nunatak-inhabiting springtail, *Cryptopygus sverdrupi*, remain in a cold hardy state all year round. However, most polar insects acclimatize to the cold in the weeks just before winter (Everatt et al., 2015). They prepare themselves physiologically and improve their low temperature tolerance. As autumn progresses, insects use environmental signals such as shortening day lengths and gradually decreasing temperatures to trigger seasonal cold-hardening adaptations. These mechanisms include dramatic changes in biochemistry, cell function and gene expression that permit improved cell function and viability at low temperature (Teets and Denlinger, 2013). Rapid cold hardening mechanisms include dramatic changes in biochemistry, cell function and gene expression that provide improved cell function and viability at low temperature.

Rapid transitions from summer to winter can leave polar insects unprepared. If they fail to achieve cold-hardiness in time, the survival of freeze-tolerant species is threatened. Such quick seasonal transitions also raise the supercooling point of freeze-avoiding species, and reduce the capacity of these animals to survive chilling injuries. However, many Arctic insects have developed a survival mechanism that allows them to cope with rapid temperature drops. This is called rapid cold hardening. This response allows insects to adjust quickly to falling temperatures within a few days or less. However, relatively little is known about the physiological mechanisms that lie behind rapid cold hardening.

DeJong and Saastamoinen (2018) studied the development of cold tolerance in a population of the Glanville fritillary butterfly (*Melitaea cinxia*) (Fig. 8) in the Åland Islands of Finland. These islands lie at the northern limit of the species' range. They measured

Fig. 8 Photo of the Glanville fritillary butterfly (*Melitaea cinxia*), used by permission of Peter Hunt.

chill coma recovery (CCR) following two temperature treatments during late larval and pupal development. When insects are cooled sufficiently, they suffer an initial loss of neuromuscular function. This is called chill coma. It is caused by decreased exchange of molecules into and out of cells. This depresses the electrochemical signals to muscle cells, causing them to lose function. The adaptation and acclimation responses that allow some insects to tolerate low temperatures involve multiple factors, several physiological systems, and biochemical adjustments (Overgaard and MacMillan, 2017). The ability to recover from chill coma is a well-established proxy for cold tolerance at the beginning of the adult stage. Then they tested the effects of both thermal treatments during the adult stage on late adult CCR. Their results demonstrate that cooler temperatures during the insect's development into an adult lead to reduced cold tolerance in the early adult stage, whereas cooler conditions during the adult stage lead to increased cold tolerance. This suggests that adult acclimation is key to this butterfly's survival in cold regions.

Freeze Tolerance and Freeze Avoidance

Insects have evolved various adaptations to cold, from avoidance of freezing temperatures to tolerance to freezing. These topics are covered in-depth in Denlinger and Lee (2010). The ability to acclimatize to cold conditions is determined by natural selection for cold adaptation. There are two physiological mechanisms by which cold-adapted insects survive freezing temperatures. The first of these is freeze-avoidance; the other is freeze tolerance. Freeze-avoiding insects range across both the Arctic and Antarctic regions, where they outnumber freeze-tolerant species in most cases. These insects can be separated into four different groups (Everatt et al., 2015). These include true freeze-avoiding taxa, for which their lower lethal temperature equals the supercooling point. There are also a group of chill-tolerant taxa that show minimal pre-freeze mortality, as well as chill-susceptible taxa that die well above their supercooling points. Finally, there are opportunistic survival taxa that are unable to survive below their developmental threshold.

For insects inhabiting cold environments, resistance to freezing temperatures allows them to occupy extremely cold regions. Most cold hardy insects develop freeze avoidance mechanisms because the indiscriminate formation of ice inside the body is lethal. The development of ice nucleators and antifreeze proteins are of critical importance for cold-hardy insect survival in winter. They survive at low temperatures by removing ice nucleating agents from their body fluids that could potentially cause spontaneous internal freezing. They also accumulate low molecular weight compounds (glycerol or other polyols) in such high concentrations that their bodies remain unfrozen, even at temperatures as low as -40°C to -60°C . Thus, they overwinter in a super-cooled state, stabilized by the production of internal antifreeze compounds. Supercooling is principally achieved via three processes, and is biochemically simpler than freeze tolerance. The first is the removal of ice nucleating agents. Another method of prohibiting ice formation inside freeze-avoiding insects is the accumulation of antifreeze proteins, as well as the production of polyols (organic compounds with multiple hydroxyl groups), sugars and amino acids. Together, these chemical compounds serve both to protect insects from freezing and to enhance their metabolic functions at lower temperatures.

Supercooling points (SCP, nucleation temperature, or crystallization temperature) of insects and other terrestrial arthropods vary greatly, from -2°C to -100°C or lower (Duman et al., 2010). Supercooling is affected by a number of factors, including the volume and water content of the organism, and the ability of the body surface to prevent inoculative freezing by external ice. Freeze-tolerant species often exhibit high SCPs (above -10°C) and have selected for extracellular ice nucleators, while freeze-avoiding insects generally have selected against ice nucleators and for antifreezes, allowing them to supercool below ambient temperatures to which they are exposed over the winter. Protein ice nucleators limit supercooling by organizing water into an ice-like structure, the embryo crystal that promotes freezing at a temperature higher than that where ice would otherwise form. Experiments have shown that this strategy lowers the supercooling point of bodily fluids by up to 20°C in some insects (Everatt et al., 2015).

Freeze-tolerance is another vital survival mechanism for insects subject to long-term exposure to subfreezing temperatures. This tolerance allows insects to survive through the use of selective internal ice formation. This induced freezing takes place at temperatures just below the freezing point of water (-3°C to -10°C) (Everatt et al., 2015), in a controlled manner that minimizes cell damage. Experiments have shown that this strategy lowers the supercooling point of bodily fluids by up to 20°C in some insects. The vast majority of freeze-tolerant insects restrict ice formation to internal body compartments outside their vital organs. This is chiefly done through the accumulation of ice-nucleating agents, including specialized proteins, food particles, crystalloid compounds, and even microorganisms. All of these act as locations of water molecule aggregation. By accumulating these agents in the hemolymph (insect blood) and gut, as well as in other tissues, ice formation is encouraged to take place outside of cells. At near-freezing temperatures, ice crystal growth is relatively slow, allowing time for water to be released from cells and join the newly formed ice crystals. Cellular fluids (cytoplasm) therefore become more concentrated and cell walls are less susceptible to splitting open because of water freezing inside them. The strategy is most often found in regions that experience extremely low winter temperatures, such as the Arctic and continental boreal regions.

Freeze-tolerant insects also produce antifreeze proteins and/or antifreeze glycolipids. These compounds stop the expansion of large ice crystals and instead promote the growth of many small crystals that do less damage to tissues. However, these compounds cannot prevent all cellular damage from ice, so freeze-tolerant insects also accumulate additional antifreeze compounds, such as polyhydric alcohols, glycerol, sorbitol, and trehalose. Within the cell, these compounds stabilize proteins and membranes, and prevent tissue freezing.

Nevertheless, freeze tolerance poses many challenges to the insect. Freezing can cause cellular dehydration and mechanical damage. As discussed above, Existence at temperatures below 0°C greatly inhibits metabolic processes. While freeze-tolerant insects accumulate many potentially protective molecules, the mechanisms underlying freeze tolerance have not yet been fully explored (Toxopeus and Sinclair, 2018). It is thought that freeze-tolerant insects survive the winter by controlling the quality and quantity of

ice that forms in their bodies, by preventing or repairing cell damage, by managing biochemical processes while frozen and while thawing, and by restoring their physiological processes after their bodies have thawed (Toxopeus and Sinclair, 2018).

Several species of insects combine both strategies. Insects of this kind are able to super-cool and at the same time be tolerant to freezing. Such insects have been found in Alaska, Canada, and Siberia. The molecular basis of this combination of properties remains unknown.

Desiccation Tolerance

An ability to tolerate water loss is crucial for the survival of polar insects that are less resistant to desiccation. Antidesiccation adaptations have a good deal in common with freeze-avoidance, including the production of polyols and sugars. Soil-dwelling insects and many immature stages of above-ground species spend most of their time in the soil. These must cope with soil ice during winter. Most of these insects have only two options for survival: either tolerate internal freezing or dehydrate. In frozen soil, there is a strong tendency for ice outside the insects' bodies to draw the liquid water out of their bodies, causing desiccation of tissues (Holmstrup, 2015). A cold tolerance mechanism that retards this process is called cryoprotective dehydration (CPD). Utilization of this protective mechanism requires an insect to withstand substantial dehydration of its bodily fluids. However, CPD is essentially a freeze-avoidance strategy, and the associated physiological traits are essentially the same as those found in freeze tolerance. Dehydration virtually eliminates the risk of tissue ice formation, ensuring survival in frozen soils. Thus, winter survival of soil-dwelling invertebrates depends more on dehydration than on supercooling. However, cryoprotective dehydration can be slow, so some supercooling capacity is needed in its initial phases (Sørensen and Holmstrup, 2011).

Case Studies of Insect Cold-Hardiness

In a study done in the Yakutia region of northeast Russia (Li, 2016), the vast majority of studied beetle species were found to be freeze tolerant (Fig. 9). The Yakutian climate is extremely harsh, even by Siberian standards. The coldest regional temperatures are below -64°C , and the long winters have sustained temperatures between -47°C and -55°C . A total of 30 insect species were investigated (Table 4), and 93% were found to be freeze tolerant. Among 22 studied species from 8 beetle families, only one, the boreal longhorn beetle *Rhagium inquisitor*, was found to exhibit freeze avoidance. In addition to beetles, all studied species flies (Diptera) were found to be freeze tolerant. Only one species of Lepidoptera, a noctuid moth, *Apatele psi*, was identified as freeze avoiding. The goat moth, *Cossus cossus*, was the only species in the study that could switch strategies between freeze avoidance in northern

Europe to freeze tolerance in Yakutia. Nearly all the insect species in Li's study were found to take shelter in thermally buffered habitats during winter.

In the coldest region of the Northern Hemisphere, the region of northeast Siberia known as the "Pole of Cold," the resident insect fauna is regularly subjected to extremely low temperatures and very long winters. Here, average January temperatures run as low as -50°C , and absolute minimum temperatures have been recorded at -70°C . Freezing temperatures may persist from October to

Strong tolerance to freezing is a major survival strategy in insects inhabiting central Yakutia (Sakha Republic, Russia), the coldest region on earth. *Cryobiology* **73**, 221–225.

Table 4 Super cooling point, ice nucleating temperature, and overwintering habits of beetle species found in central Yakutia

Species	Super cooling point (°C)	Ice nucleating temperature (°C)	Overwintering habit
Carabidae			
<i>Curtonotus torridus</i> (Panz.)	-6.0 ± 1.2	-5.9 ± 0.1	Soil litter, under snow cover
<i>Amara similata</i> (Gyll.)	-7.0 ± 0.52	-6.9 ± 0.61	Soil litter, under snow cover
<i>Pterostichus eximius</i> (Moraw.)	-9.6 ± 0.24	-9.5 ± 0.91	Soil litter, under snow cover
<i>Pterostichus magus</i> (Mannh.)	-7.5 ± 1.4	-7.2 ± 0.85	Soil litter, under snow cover
<i>Cicindela nitida</i> (Wiede.)	-7.5 ± 0.8	-7.3 ± 0.23	Soil litter, under snow cover
<i>Cicindela campestris</i> L.	-10.0 ± 0.36	-9.5 ± 1.1	Soil litter, under snow cover
Elateridae			
<i>Adelocera fasciata</i> L.	-6.5 ± 1.12	-6.1 ± 0.7	Unknown
<i>Stenogostus undulatus</i> DeG.	-8.8 ± 0.65	-8.0 ± 0.67	Under pine bark, above snow line
Cerambycidae			
<i>Monochamus sutor</i> L.	-3.0 ± 0.92	-3.0 ± 1.2	Under pine and larch bark, above snow line
<i>Monochamus urusovi</i> (Fisch.)	-6.8 ± 1.54	-6.1 ± 0.45	Under pine and larch bark, above snow line
<i>Rhagium inquisitor</i> (L.)	-33.0 ± 2.15	–	Under dead conifer bark, under snow cover
<i>Acanthocinus aedilis</i> (L.)	-18.0 ± 7.58	–	Under dead pine bark, under snow cover
Tenebrionidae			
<i>Upis ceramboides</i> (L.)	-7.5 ± 2.6	-7.0 ± 0.28	Under birch bark, some above snow line
Silphidae			
<i>Silpha carinata</i> Herbst	-8.0 ± 1.3	-7.8 ± 0.89	Inside plant debris, below snow line
Chrysomelidae			
<i>Chrysolina graminis</i>	-6.9 ± 0.33	-6.5 ± 0.25	Unknown
<i>Galerucella nymphaea</i>	-7.3 ± 0.14	-7.7 ± 0.31	In soil, under snow
Curculionidae			
<i>Hylobius albosparsus</i>	-8.5 ± 1.25	-8.35 ± 1.5	Soil litter, under snow cover
<i>Ips subelongatus</i>	-9.9 ± 0.75	-9.2 ± 0.45	Sometimes under larch bark

Data from Li, N.G. (2016). Strong tolerance to freezing is a major survival strategy in insects inhabiting central Yakutia (Sakha Republic, Russia), the coldest region on earth. *Cryobiology* **73**, 221–225.

April. A study by Berman and Leirikha (2018) focused on cold-hardiness of insects and other invertebrates in this region. They found that 30 of the 37 species of insects they studied employed super cooling to survive subfreezing temperatures. Freeze tolerance and cryoprotective dehydration were more-or-less equally employed among the remaining seven species.

Part of this study focused on the cold-hardiness of Siberian ants (Fig. 10). The lowest average super cooling point (about -40°C) is characteristic of three species of ants: *Leptothorax acervorum*, *L. muscorum*, and *Camponotus herculeanus* (Fig. 11); their capacity for significant supercooling is associated with the accumulation of 16%–20% of polyols in their hemolymph. The population of the

carpenter ant, *C. herculeanus* from the upper Kolyma River basin is more cold-resistant than North American populations from the more southern and warmer boreal regions of Canada, such as Pincher Creek, Alberta, (50°N, 114°W), where the mean SCP was -28.7°C and the glycerin content was 5.8%.

In the animals with moderate cold resistance, the winter survival mechanisms are equally diverse. For the most part, they overwinter in a super cooled state with an SCP of about -30°C . The decrease in SCP in winter can also be accompanied by the accumulation of polyols and sugars, but in a smaller amount than in the first group, for instance, up to 10% in the ant *Myrmica kamtschatica*. The species that are the least resistant to cold are characterized by SCP values in the range of -17°C to -22°C . These species also have lower quantities of low-molecular antifreezes. In the ants of the genus *Formica*, cold hardiness is ensured by a highly stable super cooled state in winter.

Conclusions

The ability of insects to live in extremely cold environments is truly remarkable, and involves every aspect of their lives, from timing of events in their annual life cycles to their behavior patterns and their internal physiology. Most of these adaptations are encoded in

their DNA, and geneticists are only now starting to unravel the location and function of genes that control the processes described in this article. In the vernacular, we would say that polar insects are *hard wired* to live where they do. However, these very adaptations to cold make polar insects and other invertebrates extremely vulnerable to global warming, which is amplified at the poles. As temperatures rise, especially in the Arctic, the native fauna of the tundra will suffer and decline. As they are already living so far north, there are no more northerly places available for immigration. The rising temperatures will cause decreased fitness in cold-hardy insects, and they will also be forced to compete with more warm-adapted insects, invading from the south. Likewise, changes in the composition of high latitude plant communities, a phenomenon already documented in many Arctic regions, will disturb the balance of tundra ecosystems, including long-established plant-insect interactions. The cold-hardiness of Arctic insects, their greatest asset for survival in previous millennia, may very well become their greatest liability in the coming decades.

Abstract

Arctic insects are a small but noteworthy group. Out of the millions of insect species in the world, only a few thousand are adapted to withstand the rigors of Arctic climate and its short growing season. There are about 3000 insect species living in the Arctic today. There is a general trend in Arctic insect faunas: decline in diversity with increasing latitude. This trend corresponds closely with the northward decline in summer temperatures, as reflected in the mean July temperature. Diptera (flies) dominate the insect fauna of all Arctic regions.

Cold intervals saw the distributions of Arctic insects shift either southwards, or into the Beringian refuge. Warm intervals saw their expansion into recently deglaciated landscapes. This natural process has repeated itself dozens of times since Quaternary glaciations began. The fossil record demonstrates that each major climatic change brings about a new reshuffling of species into specific regions. However, Arctic insects are extremely vulnerable to the current global warming, which is amplified at the poles.

Introduction

Arctic insects are a small but noteworthy group. Out of the millions of insect species in the world, only a few thousand are adapted to withstand the rigors of Arctic climate and its short growing season. Chernov (1995) estimated that there are about 3000 insect species living in the Arctic today. But it is not possible to say exactly how many insect species live there. There are several reasons for this. First, there is a lack of knowledge of the taxonomy of poorly studied insect groups, especially the families in the orders Diptera, Hymenoptera, and Lepidoptera—that is, which species are which? Second, because the Arctic is a costly region to visit, regional collections and data on regional faunas are woefully incomplete—that is, who lives there? Third, the knowledge we do have on Arctic insect systematics is confused by the large number of incompatible synonyms used by taxonomists in Russia, North America, and Western Europe—that is, what do we call them? Russian entomology during most of the 20th century developed in isolation from that of the rest of the world, leading to multiple names being given to the same Holarctic species. There is even a difference in the terminology used to describe the biological zones of the Arctic between the Russian literature and the literature from Europe and North America (Fig. 1). The High Arctic zone of Western literature is divided into the Polar Desert Zone and the Arctic Tundra Zone in the Russian literature. The Low Arctic Zone of Western literature is divided into the Typical Tundra, Southern Tundra, and Forest Tundra Zones in the Russian literature.

The dominant distribution patterns of Arctic insects fall into three categories: Nearctic, Palearctic, and Holarctic. Nearctic species are found in Arctic North America. Palearctic species are found in Arctic Eurasia. Holarctic species are found in both the Palearctic and Nearctic regions.

Trends in Arctic Diversity

There is a general trend in Arctic insect faunas: decline in diversity with increasing latitude. This trend corresponds closely with the northward decline in summer temperatures, as reflected in the mean July temperature (Fig. 2). As demonstrated by Chernov (1995), there is a very clear decline in the number of insect species between the summer temperatures associated with the Boreal zone ($>12^{\circ}\text{C}$) and those of the High Arctic zone ($<4^{\circ}\text{C}$).

Fig. 1 Differences in the terminology used to describe the biological zones of the Arctic between the Russian literature and the literature from Europe and North America. Beetles (Insecta, Coleoptera) in the Arctic fauna: Communication 1, faunal composition. *Entomological Review* **94**, 438–478.

Fig. 2 Northward decline in summer temperatures, as reflected in the mean July temperature. Data from Chernov, Y.I. (1995). Diversity of the Arctic terrestrial fauna. In Chapin, F.S. III., and Körner, C. (eds.), *Arctic and alpine biodiversity: Patterns, causes and ecosystem consequences*, pp. 81–95. New York: Springer.

There are four orders of insects that dominate arctic faunas: Coleoptera (beetles), Lepidoptera (butterflies and moths), Hymenoptera (wasps and bees), and Diptera (flies). As shown in Fig. 3, the proportion of the world's insect faunas contributed by these four orders is quite different from their relative proportions in Arctic faunas. While beetles (Coleoptera) are the largest order of insects by far (more than 350,000 described species, making up almost 40% of all known insects), they comprise only 13% of the Arctic fauna, and only 2% of the High Arctic fauna (Chernov et al., 2014). The number of known species of moths and butterflies (Lepidoptera) is about 300,000. That represents about 17% of the world's insect diversity. Their numbers throughout the Arctic comprise 11% of the insect species, and their species numbers drop to 6% of the High Arctic insect fauna. The Hymenoptera are more evenly distributed in faunal diversity. The number of species worldwide accounts for 17% of insect species, including many species of ants, which are altogether lacking in the Arctic. The diversity of wasps and bees in the Arctic accounts for about 14% of insect species, and the percent composition of Hymenoptera in the High Arctic jumps to 20% of the insect fauna. The species of lice (Phthiraptera) are relatively few in most of the Arctic, except on Svalbard (Fig. 4). Finally, flies (Diptera) account for about 18% of worldwide insect species diversity, but they make up almost half of all Arctic species, and 57% of the High Arctic insect species (Chernov et al., 2014).

The general trend among Arctic insect orders is one of decline in both diversity and abundance of species from the Low to High Arctic. However, this trend does not work the same way in all insect groups. Some orders decrease in importance or even disappear at very high latitudes (e.g., Coleoptera). In other orders, species richness changes in proportion to the overall decrease in animal diversity (e.g., Lepidoptera and Hymenoptera). A third group of taxa, such as the Diptera, maintains a relatively high level of biodiversity, and their relative contribution to the whole insect fauna increases greatly at high latitudes. This peculiar feature of the arctic fauna reflects the presence of some very-well adapted groups of arctic species. This trend is expressed to differing degrees at different taxonomic levels: classes, orders, and families.

Fig. 3 Holarctic percentage composition of insect faunas from all regions, the Low Arctic and the High Arctic. Data from Chernov, Y.I., Makarova, O.L., Penev, L.D., and Khruleva, O.A. (2014). Fig. 4 Percent composition of dominant insect families in the Arctic regions discussed in text.

Russian Arctic

In the Russian High Arctic region, dominated by polar desert, many insect groups are either absent altogether, or are represented by very few species, or even by one species. For instance, in the southern shrub Siberian tundras of Taimyr and Yamal, the ground beetle (Carabidae) fauna includes about 60 species. Throughout the Russian Arctic, there are ~139 species of beetles in 18 families

(Table 1). In the Typical Tundra zone there are 15–20 species, and in the High Arctic Tundra there are 2–6 species, with only one species found in the Siberian polar desert. One interesting trend in the Arctic beetle fauna is the increasing importance of the subfamily Omaliinae in the family Staphylinidae (rove beetles) with increasing latitude. Chernov et al. (2014) commented on this trend and noted that many omaliine staphylinids are cold adapted, and are active beneath the snow on the Siberian tundra. The only rove beetle that is found today in the polar desert zone of Siberia is the omaliine, *Micralymma brevilingue* (Fig. 5).

The southernmost of the Siberian tundra zones is the Forest-Tundra, where fingers of boreal forest (taiga) extend north into the tundra. In this region, upwards of 15 insect orders are significantly represented, especially the Plecoptera (Stoneflies), Hemiptera, Coleoptera, Trichoptera (caddisflies), Lepidoptera, Hymenoptera, and Diptera. The Russian Arctic Hemiptera fauna includes more than 75 species of aphids (Stekolshchikov and Buga, 2009). One of these is *Cavariella archangelicae*, the willow—angelica aphid (Fig. 5). Its host plants alternate between willows (*Salix* spp.) and angelica (*Angelica*).

The Russian Arctic Lepidoptera fauna includes upwards of 200 species in 18 families of moths and butterflies. The most diverse of these families are the Tortricidae (38 species), Geometridae (26 species), Noctuidae (47 species), Nymphalidae (21 species), and Satyridae (22 species) (Table 2).

Much the same pattern of insect order diversity holds true in the Southern Tundra and Typical Tundra zones of Siberia (Fig. 6). The Russian Arctic Hemiptera includes the families Miridae (2 species), Pentatomidae (5 species), Acanthosomatidae (2 species), and Aphididae (2 species). Of these, only the aphids persist into the High Arctic regions. The Russian Arctic Diptera fauna includes more than 260 species in 11 families. The most important of these are the Culicidae (12 species), Syrphidae (116 species), Tabanidae (11 species), and Chironomidae (96 species) (Table 1). The Russian Arctic is the only Arctic region where Chironomidae are not the most diverse group of insects.

However, in the Arctic Tundra zone, equivalent to the High Arctic zone in the Western literature, many insect orders are only poorly represented, and the only important orders are the Plecoptera, Coleoptera, Lepidoptera, Hymenoptera, and Diptera. It is worth noting that stoneflies are part of this group, as they are not found in the High Arctic faunas of North America, Greenland or Svalbard. Fochetti and de Figueroa (2007) note that Asian stonefly diversity is much greater than that of Europe or North America. The stonefly fauna of the Russian Far East is rich and unique, including 139 species from 45 genera and 8 families, with endemism at the generic level (Teslenko, 2009). Siberian stonefly distribution patterns fall into three groups: Beringian, East Siberian, and East Asian. The nonrelict stonefly fauna apparently originated from three primary sources: a southern source on the Asian mainland by way of the Amur River Basin, a northwestern North American source from across the Bering Land Bridge, and a western source in Siberia, including a few European taxa. Three stonefly families are found in the Arctic zones of Siberia, including three species.

The Polar Desert Zone of Siberia only has species of Coleoptera, Lepidoptera, Hymenoptera, and Diptera. These same four orders are the dominant insects throughout the High Arctic regions of the world.

North America

The North American Arctic insect fauna has been reviewed by Danks (1981). The dominant orders of North American Arctic insects are the Coleoptera, Lepidoptera, Hymenoptera, and Diptera (Fig. 7), with a smaller contribution from the Hemiptera. There are just 66 species of true bugs in the North American Arctic, including 18 species in the Canadian Arctic Islands and 6 species in the Canadian High Arctic. One prominent family of Hemiptera in the Canadian Arctic is the Saldidae, or shore bugs. These are active predators. As the name implies, they are usually found near water, in damp habitats. The moths and butterflies (Lepidoptera) are more diverse here, but there are only 162 species throughout the North American Arctic, 39 species in the Canadian Arctic Islands and 23 species in the Canadian High Arctic. Although beetles (Coleoptera) are the most diverse order of insects throughout the world, in the North American Arctic there are just 203 species, including 30 species in the Canadian Arctic Islands and 13 species in the Canadian High Arctic. The two most diverse orders in the North American Arctic are the Hymenoptera and Diptera. The Hymenoptera comprise 272 species in the North American Arctic, including 106 species in the Canadian Arctic Islands and 80 species in the Canadian High Arctic. As in the rest of the Arctic, there are no ants (Formicidae) in the North American Arctic fauna. The Arctic Hymenoptera are comprised of bees and wasps. It is worth noting that Hymenopteran diversity in the American High Arctic is six times greater than that of Coleoptera, and more than three times greater than that of the Lepidoptera. However, here, as elsewhere in the Arctic, the most diverse order is the Diptera, or true flies. There are 787 fly species in the North American Arctic, including 307 species in the Canadian Arctic Islands and 200 species in the Canadian High Arctic.

A survey of the insect fauna of Ellef Ringes Island (78°N) illustrates the paucity of most orders at such high latitudes in the Canadian Arctic. McAlpine (1965) found one species of Anoplura (sucking louse—*Hoplopleura acanthopus*—Fig. 5) that is an external parasite on *Dicrostonyx groenlandicus*, the northern collared lemming, one species of geometrid moth (*Psychophora sabini*—Fig. 5), one species of ichneumon wasp, and 26 species from 6 families of Diptera.

Most of the beetle species found in the North American Arctic are predators in the families Dytiscidae (predaceous diving beetles), Carabidae (ground beetles), and Staphylinidae (rove beetles) (Table 3). However, in the High Arctic some ground beetles are omnivorous, taking both plant and animal food. These include the highly cold-adapted species *Amara (Curtonotus) alpina* (Fig. 5). Plant-feeding families, such as the Chrysomelidae (leaf beetles) and Curculionidae (weevils) are found in the Low Arctic tundra of North America (12 and 10 species, respectively), but are not known from the High Arctic regions. Table 4 shows the distributions and known host plants of Arctic leaf beetles.

The Diptera of the North American Arctic includes 21 families, dominated by the 155 species of midges (Chironomidae) (Table 3). In the High Arctic, midges comprise more than half the insect fauna. The larvae are aquatic and thrive in shallow tundra ponds that warm in the 24-h daylight of Arctic summers. In dry arctic sites, a group of terrestrial midges complete the larval portion of their life cycle in musk-ox dung (Chernov et al., 1977). Arctic mosquitoes (Culcidae) include only 16 species, but numbers of individuals are extremely high. Individual swarms can be so numerous (thousands to millions of individuals) as to kill young caribou through dehydration (Culler et al., 2015). Fungus gnats (Mycetophilidae) and dark-winged fungus gnats (Sciaridae) are also successful fly families in the North American Arctic. Flies in both these families feed on fungi and live in damp, decaying vegetation. Some Sciaridae have atrophied wings (brachypterous). Another diverse group of flies in the North American Arctic is the Muscidae, or house/stable flies. In the High Arctic, the genus *Spilogona* is particularly abundant. The larvae of this genus prey on midge larvae in High Arctic ponds (Danks, 1981).

The moths and butterflies are not as diverse or abundant on the landscapes of the North American Arctic as the Diptera. The caterpillars of Tortricidae are leaf-rollers. In the High Arctic these attack lousewort (*Pedicularis*) and Mountain avens (*Dryas*) leaves (MacKay and Downes, 1969). Members of the butterfly family Lycaenidae (blues, coppers, and hairstreaks) include five Holarctic species found in the North American Arctic. They feed on *Oxyria* (sorrel), such as *O. digyna*, a common plant of the Arctic tundra that extends north to Ellesmere Island in the Canadian High Arctic (Danks, 1981). There are 14 known species of butterflies in the family Nymphalidae in North America. Three live in the High Arctic, where the larvae feed on *Dryas*, and the dwarf shrubs in the genera *Salix* (willow), and *Vaccinium* (blueberry). Nine species live in both the Arctic and boreal regions. The snout moths (Pyralidae) have 13 species in the North American Arctic, including eight species found only east of Hudson Bay. This huge bay has formed a very important barrier to biotic dispersal since the end of the last glaciation in Canada. The larvae of geometrid moths are known as “inchworms” because of their habit of repeatedly looping a given distance along a plant surface. More than 21 species have been found in Arctic North America, but many of these are essentially boreal species that have ranged slightly north onto the tundra. However, one species, *Psychophora sabini* ranges into the polar desert regions of the High Arctic. This is a Holarctic species, also found in northern Greenland and northern Siberia (Fig. 5). The other moth family that is reasonably well-represented in the North American Arctic is the family Noctuidae, or owlet moths. There are 25 species so far known from this region, including five species in the High Canadian Arctic. The caterpillars of some species feed on conifers in the boreal region, but then the adults fly north onto the tundra (Danks, 1981).

Greenland

The insect fauna of the largest island in the world, Greenland, includes over 700 species (Table 5). This island is nearly 10 times the size of Great Britain, but the vast majority of Greenland—80%—is covered by an ice sheet that has waxed and waned over the last

125,000 years (Fig. 8). This ice sheet varies in thickness from 2000 to 3000 m. Nevertheless, the east-central, northern, and south-western coastal regions are ice-free, along with narrower strips of land around the rest of the island. The ecological zones of Greenland are divided into three categories: Sub-Arctic, Arctic, and High Arctic. The Sub-Arctic regions of the island include southern Greenland where birch (*Betula*), willow (*Salix*), and rowan (*Sorbus*) form small woodlands. Southwest and Southeast Greenland also form part of the Sub-Arctic zone because of their relatively mild climates. The Arctic Zone includes the coasts of the northeast and northwest portions of the island. Here the climate is more severe: colder and drier. The far northern regions represent the High Arctic Zone, which is essentially polar desert.

Table 3 Summary of the composition of genera and 1503 species of the dominant orders of insects in the North American Arctic

Taxon	Arctic		High Arctic	
	Genera	Minimum Spp.	Genera	Minimum Spp.

^aParasitic groups.Data from Danks, H.V. (1981). *Arctic arthropods*. Ottawa: Entomological Society of Canada.

The Greenland insect fauna has some unique characteristics, as discussed in Böcher et al. (2015). Some orders that are of little importance elsewhere in the Arctic are better-represented here, while others that are typically important in much of the Arctic are of lesser importance here. For instance, the Hemiptera are represented by 34 species in Greenland, while there are only 46 species of Coleoptera, a little less than 7% of the insect fauna. The Lepidoptera are represented by 51 species in 15 families. Hymenoptera are one of two dominant orders, with 203 species in 16 families, comprising 29% of the Greenland insect fauna. It is interesting to note that more than half of the Hymenoptera species are ichneumon wasps: 118 species. These include 15 species thought to be endemic to Greenland. A typical ichneumon wasp of Greenland is *Cryptus arcticus* (Fig. 5). This species and other members of the subfamily Cryptinae are idiobiont parasitoids. This means that the wasps prevent further development of their hosts after initial parasitization.

Fig. 8 Map of Greenland, showing the ecological zones along the coasts. After Böcher, J., Kristensen, N.P., Pape, T., Vilhelmsen, L. (eds.) (2015). *The Greenland Entomofauna. Fauna Entomologica Scandinavica*, vol. 44, p. 881. Leiden: Brill.

The host insects are attacked during their pupal life stage, and chemicals released by the parasitic wasp larva prevent the maturation of the host while the parasite feeds on it.

There are two species of Apidae in Greenland: *Bombus polaris* (Fig. 5) and *B. hyperboreus*. *B. polaris* is a social bee that survives near freezing temperatures. This species is an important pollinator of arctic vegetation, including arctic poppies, roses, and willows. It is found in Arctic North America, Greenland and Russia. *Bombus hyperboreus* is a parasite of *B. polaris* throughout the latter species' range. Queens of *B. hyperboreus* attack the nests of *B. polaris*, killing the queen and taking over the nest. The offspring of the parasite are then raised by the *B. polaris* workers (Böcher et al., 2015).

But here, as elsewhere in the Arctic, Diptera are dominant. The Greenland fauna contains at least 349 species in 34 families. Arctic flies are important pollinators of flowering plants on the tundra. For instance, the cheese fly (Piophilidae) *Lasiopiophila pilosa* (Fig. 5) pollinates *Cerastium arcticum* (Arctic mouse-ear) in Greenland. The Greenland fly fauna includes 125 species of midges (Chironomidae), including 4 species thought to be endemic.

Chironomid Abundance and Diversity

As we have seen, nonbiting midges (Chironomidae) are typically the most diverse and often also the most numerically abundant insect group on Arctic landscapes. In one count, researchers estimated 50,000 midge larvae per m² in a Greenland lake. In addition to the 125 midge species in Greenland, there are 155 species in Arctic North America, 96 species in Arctic Russia, more than 66 species in Svalbard, and more than 73 species on Novaya Zemlya. There are several factors in chironomid anatomy, physiology, and behavior that make them so successful in the Arctic, as discussed by Lindegaard (2015). Following the progression of four larval stages (instars), midge larvae pupate. In Arctic lakes, the pupal stage survives the winter beneath the surface of frozen lakes and

ponds. All preadult stages grow rapidly under favorable conditions (warm water and abundant food) but grow much slower under adverse conditions (cold water and meager food supply). The former conditions are more prevalent in southern Greenland, while the latter exemplify northern Greenland. The pupae emerge from the ice in spring as adults. In the north, midges may persist in their immature stages for several years, slowly building the chemical energy reserves to emerge as adults. In central and northern Greenland, midges must employ strategies to survive freezing temperatures for many months of the year. The principal survival method is for midge larvae to undergo dehydration of their bodies. With water content kept to an absolute minimum, these larvae are virtually immune to the effects of cold environments. Other midges burrow deeply in the mud at the bottom of ponds and lakes, and so insulate themselves from winter air temperatures.

Arctic midges live in a wide variety of freshwater and terrestrial habitats. These range from shallow ponds to deep lakes and damp riparian habitats. The shallow littoral zone of lakes is much more productive of midge larvae than colder deep waters. In addition to their variety of habitats, Arctic midges also display a wide diversity of food preferences. Some larvae, such as the Tanypodinae, are predaceous, but the first two instars also feed on algae. Other subfamilies have mouthparts adapted for scraping algae and plant detritus off of surfaces. Midges play a key role in aquatic (freshwater) food chains in the Arctic. They contribute an average of 60% of benthic production in Arctic lakes. The lack of competition by other aquatic insect groups, especially in the High Arctic, results in the dominance of chironomids here. They are particularly important in nutrient-poor (oligotrophic) lakes, where they can make up 96% of benthic secondary productivity. Finally, colonization of new regions by midges is facilitated by their small, light-weight, winged adults. These are able to be carried great distances by winds.

Distribution Patterns of Greenland Insect Fauna

The west coast of Greenland is separated from Ellesmere Island by Nares Strait, a body of water ranging from 20 to 140 km across. So it is not surprising that many Greenland insect species are also found in Arctic Canada. All five species of butterflies exhibit this Nearctic distribution pattern, as do 6 out of 8 caddisfly species. The Greenlandic spider fauna contains 20 Nearctic species, about 10 Palearctic species, and 45 species that are Holarctic. Flies in the family Muscidae represent a mixture of Nearctic (10 species) and Holarctic distribution patterns (27 species). The beetle fauna is divided almost equally between Palearctic and Holarctic species (Böcher et al., 2015). The underlying trend here is that the insects that are strong fliers, or disperse easily, are dominated by species with Nearctic distributions, while the more earthbound taxa are predominantly Palearctic in distribution.

The postglacial colonization of Greenland by insects is somewhat easier to explain for the Nearctic taxa than for the Palearctic. For instance, the butterfly fauna of Ellesmere, once established there, could easily have colonized the deglaciated northwest coast of Greenland. But for species that have Palearctic distributions, the method(s) and timing of the immigration, presumably from northern Europe, remain obscure at best. The shortest distance between Greenland and Norway is more than 2500 km, across some of the most hostile stretches of ocean in the stormy North Atlantic. As pointed out by Böcher et al. (2015), there has not been a land bridge between Europe and Greenland during the Quaternary. Transportation by migratory birds has been mooted, but seems more likely for plant seeds than for most insect groups. Survival in situ in unglaciated refugia or mountaintops (nunataks) has also been put forward, but the glaciological evidence does not support the existence of ice-free areas on Greenland during the last glaciation. *Trans*-Atlantic crossings on drifting ice-rafted debris coming off the waning Fennoscandian Ice Sheet have also been proposed, but this seems a more likely scenario for the colonization of Iceland, which is 1000 km closer to northern Europe than is Greenland. Sadler (1999) supported the ice-rafted debris mechanism of colonization for the North Atlantic islands, and emphasized a youthful biota (hence, the lack of endemic species) and the operation of severe filters and sweepstakes during postglacial colonization. If, indeed, Greenland was colonized by European insects that managed to float for weeks or months on the open ocean before accidentally landing on the east coast of Greenland, then such a trip would represent a true sweepstakes colonization.

A good example of how cold-adapted species come and go in regional Arctic faunas is the weevil, *Isochnus arcticus* (Fig. 5). Böcher (2012) found fossil specimens of this species in sediments dating from the last interglacial period (c. 125,000 years ago). There is no obvious reason why *I. arcticus* should not have returned to Greenland after the end of the last glaciation, but it has not been found there in any modern collections. The host plant for this weevil, *Salix arctica*, is certainly widespread in Greenland today. This weevil is found today across the North American and Russian Arctic, but failed to colonize Greenland in the current interglacial.

The evidence from the Greenland fauna itself is difficult to interpret. Sadler's (1999) argument about the lack of endemic species has since been at least partially refuted by the discovery of nine endemic species of bugs, one endemic beetle species, 20 endemic species of wasps, 1 endemic flea species, and 7 species of endemic flies (see Table 5).

Svalbard

The insect fauna of Svalbard has been well-described by Coulson et al. (2014). The group of islands that make up the Svalbard archipelago are all situated in the Arctic and High Arctic zones. Svalbard is a group of five main islands that fall between 10° and 35°E and 74° and 81°N (Fig. 9). These islands include Spitsbergen, Nordaustlandet, Edgeøya (Edge Island), Barentsøya (Barents Island), and the southern outlier, Bjørnøya (Bear Island). The archipelago has a land area of about 63,000 km² of which 60% is covered by permanent ice and snow. Mean July temperature at Longyearbyen on Spitsbergen is 5.2°C. Mean January temperature is –15.3°C.

Fig. 9 Map of Svalbard.

Mean annual precipitation is only 191 mm. Air temperature is heavily influenced by the surrounding ocean currents. The northernmost extension of the North Atlantic Drift carries relatively warm water along the west side of Svalbard, while the east coast is chilled by the polar waters of the East Spitsbergen Current.

The unglaciated landscapes of Svalbard are frozen and snow-covered for 9 months of the year. Biological and geological field research has been carried out on Svalbard since the foundation of the Norwegian Polar Institute there in 1928. The scope of research activities expanded in the 1970s, with the establishment of an airport on Spitsbergen. Therefore, unlike many other Arctic regions, the insect fauna of Svalbard has been relatively well-studied. In fact Svalbard has perhaps the most complete inventory of the invertebrate fauna of any Arctic region (Hodkinson, 2013).

The dominant insect orders of the Svalbard fauna are the Phthiraptera (lice), Diptera, and Hymenoptera (Table 6). There are 41 known species of lice on Svalbard. These are all external parasites on birds and mammals. The majority of these lice attack shore birds. Some shore birds lose so many feathers to louse attack that they cannot keep themselves warm, and die of pneumonia.

There are two resident species of aphids on Svalbard, *Acyrtosiphon svalbardicum* and *Sitobion calvulum*. These aphids exhibit a number of unusual life history traits associated with life in the High Arctic, as explained by Coulson et al. (2014). Most aphids living in temperate regions have 12–20 generations per year, whereas the two Svalbard aphid species have only 2–3 generations per year. Most temperate aphids exhibit winged forms on a regular basis, whenever they experience crowding, whereas the Svalbard aphids are apterous. The development of sexual forms is stimulated by shortening day length in temperate regions, whereas the cue for development of sexual forms on Svalbard is 24-h daylight.

A mere 17 species of beetles are known from Svalbard. Of these, only three are common: the rove beetles *Atheta subplana* and *Atheta graminicola*, and the weevil *Isochnus flagellum*. These three species are widespread in the Arctic. Several beetle species identified from Svalbard are synanthropic—brought there by humans and only found living indoors. The Svalbard beetle fauna must be considered depauperate in comparison with other arctic faunas, such as that of Greenland (46 native species) or Novaya Zemlya (28 native species).

Table 6 Summary of the composition of genera and species of the dominant orders of insects of Svalbard, Franz Joseph Land, and Novaya Zemlya

Taxon	Svalbard (224 species)			Franz Joseph Land (13 species)			Novaya Zemlya (> 167 species)
